## SPECIAL PLATES.

	PAGE
Arterio-sclerosis, the Nature of (Geoffrey Evans) ... facing	456
Breast Diseases, Early and Curable (Sir G. Lenthal Cheatle) facing	927
Cyst of Right Suprarenal Capsule Removed by Operation (Sir Hamilton A. Ballance) ... facing	927
Optic Neuritis of Sphenoidal Sinus Origin (Sir StClair Thomson) facing	926
Trephination in Prehistoric Times (T. Wilson Parry) ... facing	457

## ILLUSTRATIONS IN THE TEXT.

Adrenal Glands, Function of, and its Relation to Concentration of Hydrogen Ions (Lieut.-Col. Robert McCarrison) ...	101
Adrenaline as a Potential Factor in Hyperthyroidism (D. J. Harries) ...	1015
Alsatian Bitch Suckling Six Little Pigs ...	270
Apituitarism and the Anencephalic Syndrome (D. L. Barlow) ...	15
Australian Fauna and Medical Science (William Colin MacKenzie) ...	796
Axis-Traction Lever ...	195
Ballantyne, John William ...	213
Blackbirds ...	271
Blood Transfusion (E. F. Skinner) ...	750
Brain Showing Meningeal Haemorrhage ...	565
Byron, Lord, the Lameness of ...	564
Chiene, John ...	999
Childe, Charles P. ...	935
Conjugal Ligament of a Seal ...	271
Cupping an Arab at Bou-Medfa, Algiers ...	639
Diabetes Mellitus, Treatment of (O. Leyton) ...	708
Diet Table, a Simple (H. S. Pemberton) ...	680
Eels, Various Illustrations of ...	268
Elephant Man in 1889 ...	335
Elevator for First Rib ...	637
Foreign Bodies in the Air and Food Passages (C. A. Scott Ridout) ...	413
Foreign Bodies in the Stomach Removed by Operation (A. George Brand) ...	1018
Gastric Function Modified by Drugs (T. Izod Bennett) ...	367
Herpes Zoster Ophthalmicus (Samuel Lodge and William Oliver Lodge) ...	1085
Horse-hoe Kidney (Clifford Morson) ...	237
Hunter, John ...	269
Neo-colic Intussusception Caused by Meckel's Diverticulum and Simulating Ectopic Gestation (H. H. Greenwood) ...	1016

Insulin, Influence of upon Acidosis and Lipaemia in Diabetes (H. Whitridge Davies, Charles G. Lambie, D. Murray Lyon, Jonathan Meakins, and William Robson) ...	847
Insulin, Effect of on Normal Metabolism (C. H. Kellaway and T. H. Hughes) ...	710
Intussusception Supervening on Congenital Stenosis of the Ileum (W. Turner Warwick) ...	804
Kangaroo ...	273
Laryngeal Intubation in Anaesthetics (Stanley Rowbotham) ...	1090
"Lung Splinting" in the Treatment of Pulmonary Tuberculosis (Samuel Henry Stewart) ...	415
Mnemonic Principle Applied to Biology and Psychology (Sir Frederick Mott) ...	337
Myasthenia Gravis (S. L. Heald and Arthur J. Wilson) ...	853
Nerves on the Nasal Septum ...	267
Optic Neuritis of Sphenoidal Sinus Origin (Sir StClair Thomson) ...	925
Ovariectomy in Women over Seventy Years of Age (Herbert R. Spencer) ...	583
Pasteur Centenary Celebrations: Various Illustrations ...	425 et seq.
Pedicle Forceps for Nephrectomy ...	685
Pelvic Support for Plaster Bandaging (E. Muirhead Little) ...	771
Polythelia (R. Douglas Howat) ...	929
Portsmouth and Neighbourhood, Views of ...	77, 253, 648, 1099
Rabbit's Nose, Section of, Exposing Jacobson's Organ ...	267
Radial Pulse in Intrathoracic Aneurysm (C. O. Hawthorne) ...	893
Radius, Congenital Absence of (A. P. Bertwistle) ...	325
Rectal Papillomata in <i>Schistosoma haematobium</i> Infestations (H. C. Sinderson and E. A. Mills) ...	968
Rickets, Pathogenesis of (Eric Pritchard) ...	887
Ritchie, James ...	263
Roddick, Sir Thomas ...	489
Seal of the Royal College of Surgeons of England ...	273
Splint for Median Paralysis (Walter Mercer) ...	371
Suboccipital Meningocele Successfully Removed (John Livingstone) ...	508
Thorburn, Sir William ...	576
Tibetan Anatomical Chart ...	530
Trephination in Prehistoric Times (T. Wilson Parry) ...	459
Two-button Loop Suture (W. G. Spencer) ...	970
Variations of Normal Temperature (Henry H. Haward) ...	18
Venous Pulsations and Venous Tracings (Harrington Sainsbury) ...	627
Vitamin Content of Certain Proprietary Preparations (Katharine H. Coward and A. J. Clark) ...	14
University College, London: New Institute of Anatomy (G. Elliot Smith) ...	910
Whales ...	272

## An Address ON ACUTE CONSTITUTIONAL SYMPTOMS DUE TO RADIATIONS.\*

BY  
SIR HUMPHRY ROLLESTON, K.C.B., M.D., D.C.L., LL.D.,  
PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON  
AND OF THE RÖNTGEN SOCIETY.

It is a familiar truism that any kind of treatment powerful for good may under certain conditions, such as excessive dose or undue susceptibility of the organism, do harm; this danger is much more imminent when the drug, method, or operation is of recent introduction and its potentialities and limitations as yet imperfectly explored. X rays and radium are very powerful agents and have a wide field of application in the treatment of disease; as a form of energy they exert a profound effect on metabolism, acting in either a stimulating or destructive manner according to the conditions of their dosage and the state of the body. This, of course, is obvious in the various skin lesions—dermatitis, growths, and burns—from which radiologists and their patients may suffer. The selective action of irradiations on the tissues, or the sensitiveness to rays of the various cells of the body, is important both from the point of view of treatment and of the ill effects that may thus be induced. The destructive action exerted by radiations on the blood-forming organs, especially on lymphoid tissue, has attracted much attention recently on account of the unfortunate fatalities among x-ray and radium workers.

Experimental investigations of the changes in the lymphocytes have been carried out by Mottram, S. Rass, Leitch, Lazarus-Barlow, Hess, Unger and Steiner, and others; and G. E. Pfahler<sup>3</sup> has quite recently reviewed this subject. The chronic blood changes and ill health that may occur in x-ray and radium workers are now generally recognized and guarded against. The action of radium on the nervous tissues has been much investigated since 1903 by Danyasz, Obersteiner, Alquier, and Faure-Beaulieu. In 1911 Horsley and Finzi applied filtered radium rays directly to the brain, and stated that the nerve cells were unaltered, but that from damage to the blood vessels hæmorrhages occurred. In 1922 Morowoka and Mott, from histological examination of the brains of animals whose heads had been exposed to a large amount of radium, attached importance to the protective action of the skull. Pendergrass, Hayman, Houser, and Rambo, employing various methods of acting on the brain by radium, found that the nerve cells were first destroyed and then underwent autolysis. Bone is the most resistant tissue of the body to radiations, but Regaud<sup>4</sup> found that it may show necrotic changes from x rays without any concomitant damage to the skin. The remarkable sensitiveness of the mucous membrane of the small intestine in dogs to x rays has been shown by Warren and Whipple, who found that the lymphoid tissue in Peyer's patches was much less susceptible; Lazarus-Barlow's experiments also showed that the mucosa of the small intestine of cats, rabbits, rats, and frogs was damaged by the gamma rays of radium. Warren and Whipple ascribe the grave constitutional symptoms produced in dogs by exposure of the abdomen to enormous doses of x rays to the lesion of the small intestine.

### ACUTE CONSTITUTIONAL SYMPTOMS DUE TO RADIATIONS.

*Synonyms:* Roentgen-ray intoxication; Radio-toxæmia; Mal des rayons; Disease of penetrating rays; Röntgenkatarrh.

Discussion of the acute constitutional symptoms due to radiations is appropriate at the present time when radiology is so rapidly advancing and measures of protection have

rightly been seriously taken in hand. An account of this grave ill effect of radiations necessarily entails some reference to the commoner and more or less immediate disturbance which presents resemblances in kind and indeed is difficult to distinguish from the mild type of constitutional symptoms, but is less severe and very possibly due to a different cause.

The use of x rays in medical practice, which began in 1896, was soon followed by reports of the ill effects; the skin lesions were noted in the same year, and in 1897 D. Walsh first drew attention to the constitutional effects; he recorded two such cases in x-ray workers, in one of whom the symptoms disappeared when the abdomen was shielded by lead. Since then a considerable literature has grown up on this accident, which, although in the past much rarer, and, as a rule, less serious than the skin lesions, especially carcinoma (of which according to Ledoux-Lebard there have been 100 victims among radiologists), is worthy of attention. These acute reactions are becoming more frequent with the use of massive doses of deep penetrating rays which by the "cross-fire" method of administration do not cause skin lesions. Thus, to take what it may be hoped is an extreme example: Rosenthal treated eleven cases of myeloid leukaemia by penetrating irradiations in three directions, and as a result all the patients had severe constitutional disturbance coming on soon after the treatment; three of the patients died, but the eight that survived were remarkably improved for six to ten months. Bécélère,<sup>5</sup> who quotes this paper, has had verbal information of similar cases in Germany. Inquiry from my radiological friends shows that cases of this severity are rare. Acute constitutional symptoms from the use of radium appear to be both less often noted and, when they occur, shorter and less severe than those induced by x rays (Regaud,<sup>6</sup> Desjardins). Captain A. E. Hayward Pinch of the Radium Institute allows me to quote him to the effect that he has no knowledge of acute constitutional symptoms in radium workers, but he refers to a real systemic disturbance due to auto-intoxication and characterized by slight fever and general malaise in patients, especially those with lymphosarcoma, after deep radium therapy.<sup>4b</sup> According to Bowing, mild reactions, such as malaise, anorexia, nausea, and occasional vomiting, are usually disregarded at the Mayo Clinic, but when a severe reaction occurs the radium treatment is usually omitted for two to three days.

### Onset of Symptoms.

According to the reports available, the acute constitutional symptoms may come on within a few hours or be delayed for as long as twenty days. The duration of the latent period is generally stated to vary inversely as the intensity and the length of the exposures; and usually a long latent period is followed by mild symptoms, whereas the shorter the latent period the more severe the constitutional disturbance. But there are apparent exceptions to these rules. Variation in the onset of acute constitutional symptoms may possibly be explained in the following way: that the immediate or rapid onset, on the same or next day, of symptoms such as malaise, lassitude, nausea, vomiting, headache, and giddiness, is due to a cause different from that responsible for the graver constitutional disturbance which does not come on until later.

It may be convenient to refer here to the causation of the early symptoms. Three possible factors may be mentioned: (1) Mallet and Coliez incriminate the ozone in the air of x-ray rooms; though this has been widely recognized it can hardly be the sole factor, for Hayward Pinch mentions deep radium therapy, which does not involve an ionized atmosphere, as a cause of similar symptoms. (2) Schrumph-Pierron believes that high electrical charging of the patient's body is responsible and that putting the patient to earth obviates this inconvenience; this explanation is also rendered incomplete by the symptoms seen after deep radium therapy. (3) M. Giraud, G. Giraud, and Parès<sup>7</sup> argue

\* Presidential address to the Röntgen Society, November 7th, 1922.

that the early symptoms are due to haemoclastic shock caused by destruction of leucocytes; in intensive x-ray treatment lasting for hours this would seem to be highly probable. Possibly all three of these factors may in different circumstances be operative. That auto-suggestion is responsible seems unlikely. It is reasonable to believe that the later or grave constitutional symptoms, which are due to metabolic changes in the cells of the body as a result of radiation, may sometimes be superimposed on, and so appear to be continuous with, the primary disturbance; this would be more likely to follow intensive and prolonged x-ray exposures, after which both the early and the grave constitutional symptoms are prone to occur sooner and more frequently. Cases in which the early and the late disturbances have both been noted in the same patient after an irradiation have seldom been reported; Dr. R. Knox has told me of a case manifesting both groups of symptoms with an interval separating them.

The acute constitutional symptoms are usually the same in kind, though their degree naturally differs, so that two groups—the severe and the mild—are recognizable. The symptoms are toxæmic and mainly gastro-intestinal and cardio-vascular, well-marked motor impairment of the nervous system being exceptional. The most severe cases present nausea, uncontrollable vomiting, offensive diarrhoea with the passage of blood, abdominal pain and distension, fever, which in a fatal case under my observation reached 104° F., restlessness, profound prostration, progressive cardiac failure, small rapid pulse, and dyspnoea. In one of Rosenthal's cases, fatal on the sixth day after exposure, flaccid paralysis of the lower limbs involving the bladder and the diaphragm appeared on the day before death. In fatal cases death usually occurs within a few days of the onset, thus recalling the experimental results obtained by Warren and Whipple, who exposed the abdomens of dogs to high doses of x rays from a medium hard Coolidge tube and found that the animals nearly always died on the fourth day after exposure.

Fortunately the constitutional symptoms are more often mild than severe. In these circumstances the symptoms are malaise, lassitude, loss of appetite, nausea, and occasionally vomiting, the syndrome being compared by Bécclère<sup>4</sup> to seasickness. The symptoms resemble those already mentioned as coming on shortly after the exposure to x rays and ascribed to ozone. The question arises whether or not a distinction between these latter bad effects, ascribed to the highly ionized atmosphere of x-ray rooms on the one hand, and mild constitutional symptoms due to the action of x rays on the tissues on the other hand, can be based on the interval that elapses between the x-ray exposure and the appearance of ill effects. It seems doubtful if such a distinction can be maintained, and it must therefore be admitted that it may be difficult to be certain of the exact nature of comparatively mild symptoms appearing soon after radiations.

For the following details of an example of mild constitutional disturbance in a radiologist, which appear to show that the symptoms depend on radiation of the intestines and had a definite latent period of nearly three weeks, I am much indebted to Dr. A. E. Barclay.

Starting x-ray work in 1904, he always did a great deal of screening under bad conditions and without an apron; since 1914 his private work was carried on with a Coolidge tube in the usual half-open box. In 1916, after a very prolonged course of screen examinations, often with a minimum of protection, he suffered, while working in France, from several persistent attacks of diarrhoea—sudden rushes of watery and offensive stools lasting for one or two days, gradually passing off and then coming on again. There was no nausea, and, except on one or two occasions, discomfort was absent; indeed, apart from the diarrhoea and loss in weight, he was in perfect health. Subsequently diarrhoea with much offensive flatus recurred at intervals, very occasionally being severe and accompanied by nausea and vomiting. Usually the attack started with malaise, which passed off when the bowels acted, the first motion being solid, followed about a quarter of an hour later by a liquid stool, and then by six to eight evacuations of an extremely watery character; in a few hours he would feel that all the fluid had been got rid of and he knew that the attack was at an end. On the few occasions on which casts were detected there was a burning sensation about the anus, but this disappeared completely with the evacuation of the cast. After one attack with nausea for an hour or two only and no other discomfort his weight dropped one stone, but in two weeks' time, although some minor attacks intervened, this was regained. In 1921, as the attacks were getting worse, x-ray work was given up for four months, and three weeks from the date of the last exposure the symptoms disappeared. On returning to work an attack followed after an interval of twenty days, a cast two inches long being passed; and on eight other occasions an interval of eighteen to twenty days between exposure and an attack was definitely established. The most efficient means of protection was then adopted in the form of an apron made of fairly thin lead rubber, covering the front and

back of the body. Since then he has been free from attacks, except on two occasions after examinations conducted in other x-ray departments.

#### *Site of the Exposure in Human Cases.*

Many of the instances of acute constitutional disturbance have occurred after intense radiation of the abdomen—for example, for leukaemia (Rosenthal) or for inoperable malignant disease; and according to Desjardins radiation of the upper part of the abdomen is particularly likely to be followed by acute symptoms. The exposure of large tumours far from the abdomen may also cause constitutional symptoms. It appears that radiation of the pelvis and the contained organs may reach the abdominal contents. At any rate it is admitted that constitutional symptoms, usually of a mild character, may follow radiation of the pelvis for uterine carcinoma and fibromyomas, and metrorrhagia (Bécclère<sup>5</sup>; Chambacher and Descoust; von Franz; Knox). From his wide experience Bécclère considers that the occurrence of serious lesions should be avoided by good technique and accurate dosage, but he refers to ulceration of the rectum and pelvic colon following very strong radiations by cross-firing. Similar damage to the rectum may occur in the radium treatment of carcinoma of the cervix uteri unless care is taken. In connexion with the view that the grave constitutional reactions depend on damage to the mucosa of the small intestine, attention may be called to Grunkrant's caution that, as in x-ray treatment of the pelvic organs the small intestine is traversed by the rays, the genu-pectoral or Trendelenburg position, whereby the small bowel, is removed out of the field, may with advantage be employed.

The post-mortem appearances in fatal cases of acute constitutional symptoms in man have not often been recorded. In Rosenthal's three fatal cases no morbid lesion was reported; but in von Franz's case the necropsy, performed by Orth, revealed severe ulceration of the small intestine and the colon. Bécclère's<sup>6</sup> cases of perforation and stenosis following ulceration of the rectum and pelvic colon after intensive x-ray treatment of the uterus, have already been mentioned.

#### *Cause of Acute Constitutional Symptoms.*

The cause of the acute constitutional symptoms has naturally attracted much interest and some speculation. The following views may be mentioned: (1) The bad ventilation of the x-ray rooms leading to contamination of the atmosphere with gases such as ozone and nitrous acid, produced by the x-ray apparatus. (2) That the symptoms are due to acidosis. (3) That from destruction of cells and liberation of their protein a condition of anaphylaxis results. (4) That the protein products due to cellular destruction produce an acute intoxication.

1. Pfahler<sup>7</sup> suggested that the acute constitutional symptoms depend on contamination of the air in ill-ventilated x-ray rooms by gases produced by high-tension currents. Konrich found that with ozone present in the proportion of 0.5 mg. per c.c.m. of air nausea, headache, irritable cough, and exhaustion rapidly occur and that chronic blood changes follow. But the suggestion that nitrous acid in excess in x-ray rooms is responsible for the bad effects is combated by Guthmann on the grounds that in chemical laboratories nitrous acid is present in ten times the amount that it is in x-ray rooms and yet chemists do not suffer in the way that x-ray workers do. That noxious gases must be regarded as a source of danger especially to the x-ray worker is obvious, but the bad effects ascribed to the highly ionized atmosphere of badly ventilated x-ray rooms are apparently not exactly identical with the severe constitutional symptoms, for they do not include diarrhoea or evidence of acute enteritis, and they come on very soon after x-ray exposure. Too much stress, however, must not be laid on the difference in the symptoms. Mallet and Coliez have drawn a sharp distinction between (a) the early or primary disturbance occurring the same day or the following day after irradiation, and due to the inhalation of contaminated air, and (b) the delayed onset of secondary symptoms caused by destruction of the cells of the body. The immediate effects are relatively transient, passing off in forty-eight hours, and are somewhat obviated by the administration of morphine during the exposure. Confusion may arise when an x-ray worker or patient suffering from the chronic effects (blood changes) of noxious gases is attacked by acute constitutional symptoms, which would then appear to be merely an exacerbation of the existing ill health, whereas it is in reality a second intoxication of a different character, though no doubt its incidence is favoured by the previous debility and lowered resistance. A good reason why the acute constitutional disturbance cannot be ascribed, at any rate solely, to the action of the contaminated

\* Since this address was delivered Ross Golden (*Arch. Int. Med.*, Chicago, 1922, xxx, 629) has published observations on four patients with Roentgen-ray sickness and three experimental dogs showing that there is not any evidence of aedodais.

destroyed the intracellular ferments with the exception of the autolytic enzymes. According to Richards, short exposures increase whereas long exposures inhibit or destroy ferment activity, and this view is endorsed by Peterson and Saelhof. Other observers report that radiations have no effect on enzymes (Richter and Gerhartz; H. A. Colwell).

Assuming that the enzymes are not destroyed, Pendergrass, Hayman, Houser and Rambo, in a recent paper dealing fully with the results of experimental exposure of the brain to radium, give an attractive explanation of the toxæmia which was thus produced in animals. They believe that the radiations lead to death of the nucleus and then of the nerve cells which undergo autolysis by the action of the intracellular ferments, and that the lecithin-lipoids, so abundant in the brain, are thus broken up into choline and neurine—the responsible causes of the toxæmia. They argue that the products of cellular autolysis must vary with the character of the tissues acted on by the radiations; thus when the intestines, as in Warren and Whipple's experiments, or the uterus, are exposed to radiations the resulting toxæmia will be proteolytic in nature and due to protein bodies, and so differ from the autolytic products of nerve cells described by them. Dr. H. A. Colwell, from independent investigations, has arrived at much the same conclusion, which though unpublished he kindly allows me to quote—namely, that the primary action of rays is to produce a disturbance of the colloidal equilibrium of the cell, the injured elements of which are then acted upon by the intracellular enzymes.

To sum up: it seems probable that the acute constitutional symptoms are due to flooding of the circulation with proteins liberated by the destruction of cells. Experimentally it has been proved that this can certainly be due to damage to the mucous membrane of the small intestine; clinical evidence is also compatible with this view, but also shows that destruction of cells in other parts of the body, such as large growths in the neck and in the mammary region, may be followed by acute constitutional symptoms.

#### Further Determining Factors in the Occurrence of Acute Constitutional Symptoms.

As acute constitutional symptoms are comparatively rare in ordinary practice, the question naturally arises on what further factors their occurrence depends. From Warren and Whipple's experiments, in which high doses of  $x$  rays over the abdomen constantly produced these grave symptoms in dogs, it appears that the dosage is a factor of great importance. The factor of the dosage has been generally recognized by  $x$ -ray workers, and is being more abundantly proved by the reactions seen after the Erlangen treatment. Two other possible factors may be mentioned: (1) Edsall and Pemberton argued that persons already in a toxic condition are more prone than healthy individuals to manifest acute constitutional symptoms, because they are already embarrassed in dealing with the intoxication and, if to this strain is added the metabolic labour of dealing with the complete decomposition of a large amount of broken-down tissue products, the metabolism may collapse, and in consequence signs of severe intoxication appear. This is not, as shown by Warren and Whipple's experiments, an essential condition, and as many of the patients exposed to abdominal radiation are in a toxic state but do not manifest the symptoms of acute constitutional disturbance, it cannot be regarded as a very far-reaching factor. (2) The patient's idiosyncrasy, rather vague as this influence may be, must be considered as a factor that may possibly favour the development of an acute reaction. This question has been much debated, and it appears that while there is naturally a certain amount of variation in the susceptibility of individuals to radiations and that reactions of different kinds are occasionally seen, an extreme degree of sensitiveness, comparable to other idiosyncrasies, is very rare.

Treatment is first and foremost preventive; to avoid the early transient disturbance the  $x$ -ray rooms should be properly ventilated. The avoidance of the grave constitutional symptoms mainly depends on care in the technique and dosage, but other factors may play a part, and the state of the organism must be taken into account. Proust, Mallet, and Coliez mention a red blood count below four millions and a low blood pressure as indications that  $x$ -ray therapy should be conducted with great caution. In order to avoid toxæmia Beck practises surgical exposure and surgical removal of as much as possible of the growth, and then treatment by  $x$  rays or radium of the remainder of the tumour in the open wound. In this way any discharge from the radiated tissue passes into the dressing instead of into the circulation and toxæmia

is minimized. Another advantage is that a smaller dose of radiations is required than in the ordinary method of treating deep-seated tumours. In 100 cases thus treated he had not had any death from toxæmia, whereas with the usual method four of his patients had died from toxæmia.

It is to be hoped that Auer and Witherbee's<sup>64</sup> experimental protection of the skin of rabbits against the harmful effects of  $x$  rays by the previous injection of horse serum may be applied to protect the deeper tissues of man against radiations. But before this is done further work is necessary; it is not yet known if the sensitization produced by horse serum increases the resistance of the cells of malignant growths to radiations.

When the symptoms have appeared, elimination of the toxic proteins may be assisted by diuresis, and for this purpose plenty of fluids should be given by the mouth. In conformity with his unproved hypothesis that the responsible factor is acidosis, Lange advocated the administration of sodium bicarbonate, and reported benefit from its use before and after radiation.

# A British Medical Association Lecture

## ON THE INVESTIGATION OF DYSEPTICS.\*

BY  
JOHN RYLE, M.D.LOND., M.R.C.P.,  
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

THE group of diseases embracing the various classes of dyspeptic is prevalent, and, in civilized communities, I think one may say increasingly prevalent. Its mortality rate is comparatively low, but it is responsible for much misery, inefficiency, and sick-wastage, and is by no means a trial only to its victims. From the diagnostic and therapeutic points of view it will be generally conceded that it is a difficult and unsatisfactory group; and yet if we consider and correlate the work conducted in recent years by physiologists, physicians, radiologists, surgeons, and biochemists, we must admit that great advances in our understanding of digestion and its errors have been made.

It has been my good fortune during the past three years to have opportunities of studying, both from experimental and clinical points of view, the behaviour of the stomach in health and disease, and it is my hope that I may be able to crystallize for you in some useful form the present state of our knowledge of the methods used in the investigation of dyspeptics, together with some thoughts on their relative value which I have gathered by the way.

In approaching the study of the dyspepsias we are at once confronted with a serious lack of ordered teaching and clear classification. Few of us will recollect in our student days any attempt at a scientific grouping of the dyspepsias, and many textbooks even in recent years have been content—after a discussion of ulcer, carcinoma, and gastritis—briefly to compound the remaining dyspepsias under some such vague heading as “chronic indigestion.” Attempts to classify according to symptoms have been made, and we are familiar with such designations as “flatulent dyspepsia,” “acid dyspepsia,” “fermentative dyspepsia,” “atonic dyspepsia,” and so on—all valueless and misleading titles on the whole. Even in a recent edition of a very excellent textbook of medicine we find chronic indigestion baldly summarized as follows:

“Indigestion, apart from organic lesions, is due either to irritating properties of the food or to deficiency of secretion or motility of the stomach; and these conditions may be met.”

The most satisfactory classifications of disease are those based on causal pathology. As a preliminary, therefore, to the subject under review I have drawn up a rough working classification of dyspepsias according to cause, which I have come to employ for my own purposes. There is, however, one important conception to consider even before the question of classification. It is the simple conception, now much more widely accepted than formerly, but still not sufficiently applied, that the majority of dyspepsias are not dependent on any gastric disease.

The work of Cannon with animals on the gastric responses to emotional states, such as fear and anger, and to pain, has buttressed the much older recognition in our own bodies that strong emotions, such as fear, anxiety, worry, falling in love, and depression, may upset the normal functions of the stomach. Further, if not in our own persons, at any rate in our clinical observations we are familiar with the digestive disturbances accompanying or following fatigue and infection, or reflexly induced by lesions distant from the stomach. In brief, just as with other viscera, so with the stomach it is important to realize that disturbed function as well as, and more frequently than, altered structure may produce physical symptoms. The causes which produce such disturbance of function are for the most part situated outside the viscus.

The following is a suggested classification of dyspepsias according to cause:

### Classification of Dyspepsias.

A. Dyspepsias due to organic disease of the stomach (including pylorus and duodenum)—for example, ulcer, carcinoma, gastritis, and the end-results of operations.

B. Reflex dyspepsias due to organic disease elsewhere in the alimentary tract—for example, gall stones, appendicitis, etc.—and to central nervous disease.

C. Dyspepsias resulting from the failure to lead a physiological life—for example, overeating, undereating, inefficient mastication, drinking, smoking, overworking and lack of exercise, constipation.

D. Dyspepsias due to general states of ill health—for example, early active and chronic latent tuberculosis of the lungs, anaemias, states of debility associated with muscular hypotonus, loss of natural fat deposits, and consequent visceroptosis.

E. Dyspepsias due to nervous tricks, emotional unbalance, nervous exhaustion, worry and anxiety states; and including air swallowing, hysterical regurgitation and vomiting, overconcentration on digestive processes, attempts to express a psychological unbalance as a physical abnormality, undue appreciation of normal processes in apprehensive individuals, etc.

I was interested to ascertain how satisfactorily cases would fall into these groups. Two hundred and sixty-seven unselected cases were analysed. Of these ninety were from my own records and the remainder from the records of cases under the care of Dr. A. F. Hurst, in the investigation of which it was my privilege to co-operate. They fell well into the various groups, with the exception that Groups C and E were naturally inclined to overlap. The percentage incidence of cases in the various groups was as follows: Group A, 33 per cent.; Group B, 18 per cent.; Group C, 12 per cent.; Group D, 12 per cent.; and Group E, 24 per cent.

As a large proportion of these cases had been expressly referred to us for fuller investigation, it would seem fair to assume that Groups A and B in our series probably contained a much larger percentage than they would contain in the total population of dyspeptics. Furthermore, the series includes a certain proportion of cases of gall-bladder and appendicular disease in which the symptoms were local rather than gastric.

You will note that I have made little mention of food *per se* as a cause of dyspepsia, and I would put it forward as a second useful conception, in spite of lay beliefs, that food is one of the rarest causes of chronic indigestion. Gross overeating may cause dyspepsia; injudicious dietary may aggravate a dyspepsia; certain patients have certain food idiosyncrasies; dietary and the preparation of food undoubtedly play a very important part in the treatment of many dyspepsias—all of these we may confidently assert; but it would help us in our inquiries and our treatment if we were to give food an insignificant position among the actual causal factors in dyspepsia. When dealing with the dyspnoea symptom group we look for the causes in some disturbance of respiratory, cardio-vascular, or excretory function, or in impaired oxygen-carrying power of the blood; it is only under exceptional conditions that we blame the atmosphere. In dealing with the dyspepsia symptom group we would—notwithstanding the variability and abuse of civilized diets—do well to seek for other causes of disturbed physiological balance before blaming the qualities of the food or the cook.

### CLINICAL INVESTIGATION.

So much by way of preamble. Of all the methods of inquiry in dealing with dyspeptics the clinical examination remains, and will remain, the most important; of this the most valuable part is the interrogation of the patient. It includes the customary questions with regard to family and previous personal history, and the formation of some estimate of the patient's environment and his physical and psychical reaction to that environment. It includes a collection and analysis of his subjective symptoms, and although the value of these is very variable and depends much on individual intelligence and psychology, I would regard the subjective symptoms in the majority of cases as providing more useful guidance than anything else in the clinical survey. But a collection and analysis of symptoms to be really helpful demand an appreciation of the significance of symptoms. I propose, therefore, briefly to discuss the physiological significance of such common symptoms as epigastric pain and discomfort, fullness, vomiting, nausea, flatulence, loss of appetite, furred tongue, “heartburn,” and “acidity.”

Epigastric pain may, of course, be due to other than gastric phenomena, and is met with, for instance, in cardiac and gall-bladder disease. When originating in the stomach it is, according to modern views, associated with a general or local increase in intragastric tension, commonly resulting from pyloric or gastric spasm, which impedes the onward passage of fluid, gaseous, or semi-solid contents. In short, it falls into line with other pains produced in hollow viscera; for whether we are concerned with angina pectoris, renal colic, or the pain of duodenal ulcer, we are not far from the truth in claiming that the pain is due to an abnormal increase in

\* Delivered before the Bournemouth Division of the British Medical Association.

intravisceral tension, and that in each instance the pain is best relieved by factors calculated to lower intravisceral tension. Amyl nitrite, which lessens the peripheral resistance by vasodilatation, passage of a calculus, food or belladonna overcoming the reflex hypertonus of the pylorus, are all examples of these relieving factors. Gastric discomforts are due to abnormal motor behaviour falling short of that requisite for the production of actual pain. I find it a useful leading question to put to patients complaining of epigastric pain, "Is it really pain or would it be better described as discomfort?" Real pain is always much more suggestive of an organic lesion than vague discomfort.

A sense of fullness may be present in both hypertonic and hypotonic stomachs. A man with an abnormally hypertonic gastric musculature may feel a great sense of fullness after meals, the muscle here being responsible for the tension. On the other hand, in atonic and dropped stomachs feelings of fullness and heaviness are often experienced, the food in this case, inefficiently propelled and churned, producing the sense of tension by its weight. On the whole, fullness is more often a symptom of hypotonic than hypertonic gastric musculature.

*Vomiting*, apart from that which is due to organic narrowing of the pylorus or mid-gastric area, may result from reflex spasm at either site, though the act of vomiting itself involves the co-operation of the diaphragm and abdominal muscles. The stimulus to vomit in dyspeptics may be an organic lesion, such as an ulcer, gall stones, or appendicitis; or it may be emotional; or there may be an emotional exaggeration or perpetuation of vomiting originally due to an organic cause.

*Nausea*, which is peculiarly frequent in gall stones, pregnancy, and alcoholic gastritis, and not very frequent in other dyspepsias, may also be regarded as a symptom of reflex disturbance of motor function. It is a symptom at present inadequately investigated. It may be associated with pyloric closure or failure to relax, patency of the lower oesophagus, and inhibition of normal peristaltic activity, but this needs confirmation. It appears to be felt partly as a general malaise, partly in the stomach and partly in the gullet, and may certainly be induced by mechanical irritation in the gullet.

*Flatulence*.—There are two kinds of gastric flatulence—the common odourless and tasteless variety, and the variety with a bad odour and taste. The latter, if persistent and particularly when it has the odour of sulphuretted hydrogen, is of serious import in that it suggests considerable gastric delay such as is produced by pyloric obstruction. It is more likely to be produced by carcinomatous obstruction than a cicatricial one, though I have seen it in both. Fermentation—in spite of the frequency with which it is diagnosed—does not occur in the stomach except in the presence of delay. In a very long series of fractional test meals I have never seen fermentation occurring in any of the specimens withdrawn excepting in cases of pyloric stenosis. Fermentation and decomposition are most likely to occur in the presence of a growth on account of the deficient or absent secretion of hydrochloric acid. Apart from the carbonic oxide swallowed with effervescing drinks and minute quantities evolved by food, odourless gastric flatus is generally the result of air-swallowing, or aerophagy. Aerophagy may be a result or a cause of dyspepsia, and is especially common in nervous individuals. In its major form it produces frequent and explosive belching at a rate which could not possibly be accounted for by any fermentative process, and active swallowing movements may be seen and heard.

*Appetite* is partly a psychic and memory phenomenon, but in part probably depends on gastric tonus. Good appetite means good tonus; bad appetite means poor tonus. Hunger expresses peristaltic activity. In duodenal ulcer with hunger pain there is nearly always hypertonus as well as active peristalsis, and actual appetite is not impaired, although the patient may become afraid to eat.

*Furred tongue* commonly suggests hypotonus and hyposecretion in the stomach, and possibly hypotonus of the cardiac sphincter. It is present, therefore, in febrile states with loss of appetite, in chronic gastritis, growth, constipation, and in neurasthenic dyspeptics. It may also be due to local oral disease.

*Heartburn and acidity* are difficult symptoms, chiefly because they are loosely employed to describe a variety of sensations. True heartburn is a retrosternal sensation probably dependent on spasm of the lower oesophagus or cardia. "Acidity" is the regurgitation of sour or bitter fluid into the throat, but it is not by any means necessarily associated

with hyperchlorhydria, for I have seen it in cases of hypochlorhydria, and even in achylia. It has been suggested that it may be due to organic acids or alcohols.

With the exception of this last symptom, which is not truly a gastric symptom, I am doubtful whether any dyspeptic sensations can be directly attributed to secretory abnormalities. Hurst showed that the only chemical substances capable of stimulating gastric sensations were the alcohols, and that the gastric mucosa was insensitive to all other stimuli. On theoretical grounds and for practical purposes it is justifiable to presume that all or most gastric symptoms (not including referred pains) are expressions of abnormal motor behaviour. In summary I would say that gastric pains and discomforts are usually an expression of disturbed tonus or peristaltic rhythm, with resultant general or local variations in intragastric tension.

The importance, in the course of the interrogation, of inquiring into the time incidence of pain or discomfort and the main aggravating and relieving factors cannot be overstressed.

#### THE PHYSICAL EXAMINATION.

The physical examination of the abdomen in dyspeptics, except in cases presenting gross changes, such as tumours or extreme gastric dilatation, or definite local tenderness as in ulcer, is usually regarded as disappointing. There are, however, secrets which a careful examination of the abdominal parietes may reveal, and the patient's initial gesture when asked to locate his symptom should never be ignored. A definite localization with a finger or two is much more likely to indicate organic disease. An indefinite indication with a whole hand will direct attention to Groups C, D, and E before Groups A and B.

I have interested myself of late in the referred signs of intra-abdominal disease, and have come to examine for the following signs almost as a routine:

1. The abdominal reflex in all four quadrants, noting exaggeration in any one quadrant.
2. Superficial skin soreness in any quadrant, as evidenced by wincing or complaint during testing for 1.
3. Deep skin soreness, elicited by plucking up the skin and subcutaneous fat between the finger and thumb in each of the four quadrants in turn.
4. Muscular guarding, appreciated by very gentle palpation in each quadrant.
5. Deep tenderness in the mid-line between the recti and in each quadrant.

The presence of any one, and still more of several, of these signs helps to confirm a suspicion of organic disease, but their absence does not by any means exclude it. They are most frequently useful in gastric and duodenal ulcer and, along with certain other reflex signs, in disease of the gall bladder.

If there is one point above others which I should like to emphasize it is the importance of examining patients, whenever possible, at a time when their pain or symptom is present, or even of endeavouring to produce the symptom in obscure cases. At these times they do not have to rely on memory for their descriptions, and reflex signs are more likely to be manifest. I believe that these reflex signs are not indisputably present except in association with an organic lesion.

#### ACCESSORY INVESTIGATIONS.

The last quarter of a century has witnessed the rapid development of numerous accessory methods applicable to the investigation of gastric behaviour. Their combined value is now very considerable, but they have in many ways exerted a bad influence on clinical medicine. Too much has been expected of each test as it has been evolved, and, notwithstanding that there are many cases in which an accurate opinion can only be arrived at with their aid, it cannot be too emphatically stated that they should be looked upon as contributory and not as diagnostic tests.

The most useful of these methods are radiography with opaque meals, the test meal, and the examination of the stools for evidence of bleeding in the upper gastro-intestinal tract.

#### Radiography.

It would be outside my province and beyond the scope of this lecture to discuss radiographic technique. The information obtained from radiography may be roughly divided into direct and indirect information. Direct information comprises the visualization of a definite niche or crater in gastric ulcer, of filling defects in carcinoma, and the demonstration of delayed emptying in obstructive lesions. Indirect evidences are provided by observations as to size, shape, position, tonus,

and peristaltic activity of the stomach. In other words, apart from the direct evidences, radiography is mainly employed as a test of motor efficiency. With regard to emptying rate, the normal variations have been sufficiently established, but the normal variations in size, shape, position, tonus, and peristaltic activity are so considerable in different individuals and in the same individual under different conditions that much caution is necessary before accepting opinions based on radiographic appearances. Radiography with a barium meal is of very real value in confirming a suspicion of ulcer of the lesser curvature, of which a niche or crater, often with an opposing spasm, is strongly indicative. It is of less direct value in duodenal ulcer, and we should hesitate to accept deformities of the duodenal cap as evidence of ulceration. However, a high placed, hypertonic, transverse stomach with tenderness over the cap lends strong support to a clinical suspicion of duodenal ulcer. Although frequently confirmed by radiography, carcinoma ventriculi, especially in early cases, cannot be excluded by a negative x-ray report.

#### The Test Meal.

Ewald's test meal, in which the stomach contents are withdrawn for measurement and analysis one hour after a breakfast of tea and bread, has now been widely supplanted by the fractional test meal. This method was described by Rehlfuss in 1914. I started to test its value in this country in 1919, and after three years' experience of the method am satisfied that it provides much more information than older tests, and that it should be used preferably to them in the routine investigation of dyspeptics. If radiography is accounted the best test for motor efficiency of the stomach, the fractional test meal may be accepted as an equivalent test for chemical efficiency, and it has the added advantage that it also supplies reliable evidence in regard to emptying rate. It provides information as to the amount, chemistry, and cytology of the fasting secretion; the free and total acidity throughout the meal (the results of the analyses being plotted as a curve), the regurgitation of bile, the rate of disappearance of starch, the presence or absence of after-secretion, and the presence or absence of blood at various stages. A standard meal of oatmeal gruel is employed, and specimens are withdrawn at intervals of a quarter of an hour through an Einhorn or Rehlfuss tube or a modification of these which I have had designed.

Excepting in pyloric obstruction the fractional test meal is not a diagnostic test. In the presence of obstruction it will often decide whether a cicatrized ulcer or a carcinoma is the cause. Characteristic climbing hypersecretory curves with clear acid resting juice are found in a high percentage of duodenal ulcer cases, but the findings merely express a reflex pyloric hypertonus with prevention of duodenal reflux, and may also be obtained in cases of gall-bladder and appendicular disease, in tabes dorsalis, and in some emotional dyspepsias. Achlorhydria is almost constant in early and late stages of Addison's anaemia, is frequent in carcinoma ventriculi, in which case intimately diffused blood is commonly present in several specimens, and is also met with in a higher proportion than normal of dyspepsias due to chronic gall-bladder or appendicular infection.

Impressed with the importance of a knowledge of the normal variations, I undertook in 1920, with T. L. Bennett, the investigation of 100 healthy students. Among these we found four men with complete achlorhydria, and a small group showing such degrees of hyperchlorhydria as to have stamped them, on older beliefs, as definitely pathological. Nevertheless, 80 per cent. of the men examined provided what we refer to as an "average normal" type of curve; and it is upon a knowledge of this group and the departures from it that we have come to base our opinion of the test-meal findings in dyspeptic subjects.

If radiography is more helpful in establishing a positive diagnosis of lesser curvature ulcer, I would suggest that the fractional test meal is more useful on the whole in confirming a diagnosis of duodenal ulcer. In any suspicion of growth both methods should always be employed.

I hope that I have made it apparent that, excepting in certain fairly definite and organic disease states, the evidence supplied by x rays or test meals needs careful weighing, and should be regarded as contributory evidence only.

#### Other Investigations.

Other special investigations include examination of the stools for occult blood by the benzidin, guaiac, or spectroscopic tests; the estimation of the haemoglobin in the blood,

especially in suspected carcinoma and anaemia; radiography of the chest when there is suspicion of latent tuberculosis; radiography of the whole gastro-intestinal tract; radiography of teeth and alveolar margins; and in suspected chronic appendicular trouble Bastedo's inflation test, in which pain may be produced in the appendix region by inflation of the colon with air. It will be manifest that the main function of all these tests is to confirm or allay a suspicion of some kind of organic disease.

#### THE INDICATIONS FOR A COMPLETE INVESTIGATION.

It will be asked what should be regarded as the indications for a complete investigation. I would suggest the following:

1. Any suspicion of cancer—for example, dyspepsias starting for the first time during or after middle life; dyspepsias at any time in adult life with considerable loss of weight or anaemia.
2. Suspicion or presumption of ulcer, gall stones, cholecystitis, or appendicular disease; especially with a view to deciding between medical and surgical treatment, and most especially with a view to avoiding exploratory operations.
3. Suspicion of early active or chronic latent pulmonary tuberculosis or of grave anaemias.
4. Failure of treatment in any other group.

*The most important single symptom: calling for full inquiry is genuine persistent or recurrent pain.* You may also ask whether under ideal conditions we should investigate all dyspepsias fully by modern methods. My answer would be emphatically in the negative, for that would imply confession of a serious loss of clinical sense, balance, and self-reliance, and there are, moreover, certain circumstances in which a complete investigation is actually contraindicated. I would suggest the following contraindications:

1. Cases falling obviously into Group C or E in which common-sense methods and optimism or a new mode of life are likely to achieve a cure, unless it is decided that a complete examination is necessary to remove a phobia.
2. Cases (usually falling into Group E) of the hypochondriacal type, which are likely to be made worse by further probing into their gastro-intestinal functions—that is to say, the same type which delights in abdominal operations. Reinvestigation in these cases may be almost as bad as reoperation.
3. Cases too ill for prolonged examination.
4. The patient's pocket. In other than hospital patients this is often a serious consideration, and it may well be justifiable to try a preliminary course of treatment in accordance with the presumed diagnosis, or to recommend a partial investigation. In some cases, however, a complete investigation may obviously save subsequent expenditure.

I will now attempt to summarize for you the important features of the various groups of dyspeptics. You will appreciate that it is impossible to give more than a bare outline of the picture in each case, and that in no other class of cases are individual variations and problems so numerous.

#### Groups A and B.

**Gastric Ulcer.**—Comparatively high incidence in women. Mid-line and left-sided pain and tenderness, with a gravation by food. Soreness, guarding, and increased reflex on the left, especially during pain. Relief by rest, vomiting, diet, alkalis. A normal or low curve of acidity, unless the ulcer is close to the pylorus. A normal or hypotonic type of stomach, with a niche or crater on the lesser curvature and sometimes an opposing spasm. Occult blood in the stools. A poorer tendency to recovery, both with medical and surgical measures, than duodenal ulcer. Tongue usually clean.

**Duodenal Ulcer.**—High incidence in men, particularly in the period of physical and mental vigour. Family history of duodenal ulcer or hunger in a small proportion of cases. Tendency to heal and recur spontaneously, and especially to recur in autumn and winter. Hunger pain, night pain, and relief by food. Mid-line and right-sided pain and reflex signs. A climbing hypersecretory curve. Occult blood. A high placed, hypertonic, transverse stomach with tenderness over the cap. Good tendency to recovery on rest and ulcer diet and after gastro-jejunostomy. Tongue generally clean.

**Carcinoma.**—Age incidence. Absence of previous dyspeptic history in most cases. Pain more constant than in ulcer and less definite food relationship though generally aggravated by food. Less readily relieved by rest. Sometimes pain absent throughout and general and anaemic symptoms predominating. Greater frequency of anorexia, nausea, vomiting, furred tongue, and eructations of sulphuretted hydrogen than in other conditions. Low acid curve or complete achlorhydria. Wide gap between free and total acidity. Blood cells and organisms in gastric juice. Persistent occult blood in stools. Filling defects or rigid tubular stomach. Tumours and glands.

**Gastritis.**—One of the commonest diagnoses, but a comparatively rare cause of dyspepsia. Most cases diagnosed as gastritis turn out to be ulcers or functional dyspepsias. Association with alcohol and gross oral sepsis. Acne rosacea and red nose. Loss of morning appetite; morning nausea and sickness. Diffuse burning type of pain, not so accurately localized as in ulcer. Heartburn, eructations, and tendency to diarrhoea. Low or absent free acid. Excess of mucus and cells. Furred tongue in active phases.

**Gall Stones and Cholecystitis.**—History of colic or jaundice in a small proportion of cases. High incidence in women. Pregnancy and typhoid predisposing and fatness and increasing weight common. Vomiting, nausea, flatulence, distension. Epigastric pain, right subcostal pain, scapular, interscapular, or shoulder pain. Tendency to diarrhoea or diarrhoea sensations. Shiveriness or slight pyrexia in attacks. Aggravation by exertion, jolting, and menstrual periods. Right subcostal tenderness and catch in breath on deep palpation. Referred tenderness over dorsal spines and eleventh right rib behind. Guarding of right upper rectus and impaired entry at right base in attacks with infected gall bladder. X rays seldom helpful. Hyperchlorhydria and achylia both more common than in normal subjects.

**Chronic Appendicular Dyspepsia.**—Too freely diagnosed. History of possible acute attacks. Epigastric pain without such definite food relationship as in ulcer, but sometimes closely simulating ulcer. Pain in epigastrium on pressure over appendix. Tenderness over appendix shadow when visualized with x rays. Positive inflation test. High curves and achylia both more frequent than in normal series.

**Post-Gastro-enterostomy Dyspepsia.**—This may be the result of gastric discomforts associated with an inefficient or too efficient stoma and consequently with feelings of fullness or empty feelings. It may be due to persistence or recurrence of the original ulcer or to the development of a jejunal ulcer, in which case the maximum tenderness may be found over the stoma, is usually to the left of the mid-line, and commonly at a lower point than obtains in gastric ulcer. In jejunal ulcer there is commonly a persistent high acidity. Fractional test meal shows bile in all specimens after most gastro-enterostomies, but with an unsatisfactory loop bile may be absent in many specimens. Another type of post-gastro-enterostomy dyspepsia is due to too rapid filling of the small bowel. The symptoms are usually discomforts around the umbilicus and below the area of gastric sensibility.

#### Group C.

Symptoms usually vague. Discomfort rather than pain. Fullness and feelings of weight in epigastrium. Flatulence. Aggravation by prominent causal factors and relief by healthier life, holidays, etc. In fatigue dyspepsias loss of appetite common. Physical examination may show too fat or thin a subject, but local examination negative.

#### Group D.

History or family history of tuberculosis, or debility in some cases. Poor appetite, especially in morning, with active disease. In latent disease fullness and discomfort, often aggravated by food, and tending to be worse at the end of the day. A tendency to remain below normal weight or to lose slightly. General tendency to fatigue easily. Prompt improvement in appetite and disappearance of symptoms on rest in bed and feeding up. The following is a good example of this type of dyspeptic:

A middle-aged lady who was leading a very active and useful life complained of flatulence and discomfort after food which had failed to respond to ordinary measures. Her appetite was fair, but she was afraid to eat because of the discomfort, which at times amounted to actual pain in the epigastrium. Seventeen years previously she had had a cough for a short time, and on one occasion tubercle bacilli were found in the sputum. Since then she had had no cough nor chest symptoms. The gastric investigations were negative. X-ray photographs of chest showed increased root-shadows on the right and small opacities at both apices. There was no pyrexia, cough, nor pain in the chest, and there were no physical signs of active lung disease. She was treated by rest, fresh air, and a liberal diet, which she tolerated well as soon as she rested. Six months later she had gained in weight, from 8 st. 2 lb. to 10 st. 7 lb., and had lost all symptoms.

I have seen several similar cases in which no chest trouble had ever been suspected. It is a type of case which is apt to be treated with a belt, diet, or gastric medication, but when once the cause of the debility to which the gastric mechanisms have reacted unfavourably is recognized the treatment becomes obvious, and the results of treatment are good. In the anaemic dyspeptics heartburn, acidity, poor morning appetite, and a tendency to diarrhoea are common. Relief is given by rest, treatment of the anaemia, and hydrochloric acid.

#### Group E.

Cases in this group vary from the old man who is concerned about the furring of his tongue to the young woman with hysterical vomiting; from the sufferer from simple aerophagy to the poor victim who blames every cause but the true one for his miseries, and weeds out of his dietary one article of diet after another until he is on starvation rations. The prospective, the worried, the overworked, and the indolent are numbered in the group. There is greater aggravation by anxiety and worries than by physical factors. Pain as a rule is not localized, and the whole hand is employed in the demonstrative gesture, or there may be several pains. In aerophagy left subscapular pain is not uncommon. Subjects may be "nervy," hypertonic, and restless, or they may be hypotonic and depressed. Phobias of internal disease are frequently present. There is aggravation by directing interest and treatment towards the stomach. Relief by explanation, encouragement, unearthing sources of worry, discouraging hurry and worry (especially in the neighbourhood of meal times), teaching relaxation, bromides, and sensible life and dietary. Surgery spells ruin.

#### CONCLUSION.

I have, with intent, entitled my lecture "The investigation of dyspeptics" rather than "The investigation of dyspepsias." In no branch of medicine is it more important to preserve the

wide view—to examine the patient as a whole rather than to concentrate upon his viscus. It is extremely difficult to remain balanced if one employs any single method of inquiry to the exclusion of others—if one comes to rely too much on accessory tests, or too much on clinical tests. I do not believe that there is, or ever will be, a place in medicine for such a specialism as gastrology. If the broad classification which I have outlined has a sound basis it would seem that probably less than one-third of all chronic dyspepsias are due to disease of the stomach, and even in many of these the primary factors have been situated elsewhere.

The introduction of chemical and radiographic diagnostic methods has been of inestimable value, but I believe that the chief value of these methods will finally be in the direction of helping us better to interpret symptoms and so to become more skilled at clinical diagnosis.

The works of Cannon and Carlson in America and of Hurst in this country have supplied a basis for gastro-intestinal symptomatology which has made it possible to study dyspeptics scientifically from the clinical point of view; much in the same way the work of Mackenzie and Lewis has enabled us to study cardiac manifestations reasonably and physiologically. Clinical investigation, we may now affirm, is coming back into its own. Although we shall not hastily relinquish new methods, and although we shall certainly improve upon and add to them, we must admit that we are still in the process of learning to assess them at their proper value. In the dyspepsias, as in other diseased states, it is a truism that early and accurate diagnosis is the first essential for adequate treatment. Early diagnosis depends on appreciation of possibilities and causes and on good clinical sense; accurate diagnosis in many of the dyspepsias can only be arrived at with the aid of routine investigations, the nature and scope and relative importance of some of which I have endeavoured to define. In the past we have commonly had to content ourselves with treating symptoms such as pain, flatulence, and "heartburn." Careful investigation nowadays enables us more and more frequently to discover and attack the causes of these symptoms.

## FURTHER CLINICAL EXPERIENCE WITH INSULIN

AND

A. A. FLETCHER, M.B.Tor.

(From the Department of Medicine, the University of Toronto, and Toronto General Hospital.)

In this article no attempt is made to give a review of the history of the use of various pancreatic preparations in the treatment of diabetes mellitus. A careful survey of the literature published previous to the use of insulin\* indicates that all attempts to obtain a potent pancreatic preparation suitable for the continued treatment of this disease have failed. Many investigators have reported temporary success in the treatment of diabetes mellitus with pancreatic preparations. Owing to the lack of adequate dietetic and chemical control in the treatment of these cases it is difficult to determine the exact significance of their results.

Mention, however, should be made of the work of Zuelzer. In 1908 Zuelzer and his associates reported their results in the treatment of six cases of diabetes mellitus with a pancreatic extract obtained by expressing the juice from the pancreas, treating it with alcohol, and evaporating the filtrate to dryness. The residue, which contained the active principle of the pancreas, was redissolved in salt solution or water and given by injection. Following the intravenous injection of this extract in five diabetic patients kept on a fairly constant diet, the excretion of acetone, diacetic acid, and sugar in the urine decreased or entirely disappeared. An improvement in the general condition of all patients treated was observed following the injection. In four cases the excretion of acetone,

\* A general statement of the physiological and therapeutic effects of insulin, by Professor J. J. R. Macleod, was published in this JOURNAL November 4th, 1922, p. 833.

diabetic acid, and sugar in the urine returned to the former level in from one to four days after extract treatment was discontinued. The fifth case, which was complicated by a large carbuncle, was treated by incision of the carbuncle and by the extract. After the wound healed the urine of this patient remained free of sugar and acetone upon dietetic treatment alone. The intravenous injection of the extract in these five cases was accompanied by severe chills, fever, and occasionally vomiting. In 1909 Forschbach,<sup>2</sup> working in Minkowski's clinic, reported his results in the treatment of two cases of diabetes mellitus with the Zuelzer extract, which he obtained from the Schering Company of Berlin. In one case no effect was observed; in the other the administration of the extract, which was accompanied by chills and fever, reduced the excretion of sugar to one-fifth for a period of forty-eight hours. The writer attributes the positive effect obtained in one case to the use of a freshly prepared extract. Owing to its extreme lability and the severe toxic reaction following its administration the extract prepared by Zuelzer did not come into general use in the treatment of diabetes mellitus.

#### THE TORONTO RESEARCHES.

In March, 1922, a preliminary report<sup>3</sup> was published on the treatment of severe cases of diabetes mellitus with insulin. It was then noted that insulin could bring about certain definite clinical results. The excretion of sugar in the urine decreased and sometimes completely cleared up. Coincident with the decrease in sugar excretion was a lowering in the blood sugar level, and this level could be brought down to normal or even further by careful adjustment of dosage. Ketone bodies usually disappeared from the urine in twenty-four to forty-eight hours. An increase in the respiratory quotient following insulin injection gave evidence of increased carbohydrate utilization. The patients themselves gave abundant testimony of clinical improvement; their feeling of well-being during treatment, along with the improvement in their physical and mental activity, made it appear that the symptoms which are the immediate result of this disease could be relieved by insulin administration. The effects observed in depancreatized animals following the administration of insulin have been confirmed in cases of diabetes mellitus.

Since the preliminary announcement in March, 1922, applications for treatment have been received in considerable numbers. Among these applications were many from patients with severe diabetes who had been under observation for long periods on well-controlled diets, but with a gradual failure of clearance for carbohydrates. In view of the limited quantities of insulin available, the need of these patients for relief, and the fact that such patients only can furnish satisfactory data for the establishment of our main propositions, it was decided to confine attention to these severe cases, reserving for future study and treatment the less severe ones. Consequently we are not in a position, at the present time, to furnish any data on a very interesting group of patients whose disease is in the early stage, and who may ultimately show very great degrees of functional repair of the pancreas when the latter is allowed a considerable period of relative inactivity as a result of treatment.

A general plan of investigation and treatment of patients has been adapted provisionally to determine those who require treatment with insulin and the requisite dosage to be employed. On admission to hospital the history and physical condition of each patient is investigated. Patients admitted in coma or in the precomatous state, whether of the accidental type occurring with a good tolerance or as a sequel to slowly deteriorating carbohydrate tolerance, are immediately given insulin treatment. For other cases a diet based upon the normal basal calorific requirement for the age, height, weight, and sex of the patient is calculated.\* This diet contains sufficient protein to maintain nitrogenous equilibrium and carbohydrates and fats in such a ratio as to avoid the excessive production of acetone and diacetic acid. Placing patients on fasting for a day has helped to attain constancy of sugar

Patients are kept in bed for a variable session to hospital, and afterwards only light exercise is permitted. Examinations of the blood and urine are carried out daily for a period of a week or more. At the end of this period on a constant diet the patients who are sugar-free are advised to continue dietetic treatment in view of the shortage of insulin. Those who are showing decided

glycosuria and hyperglycaemia, with possibly various degrees of acidosis in addition, are selected for insulin treatment.

Having a preparation of insulin known to be potent and to contain approximately one unit to one cubic centimetre according to the pharmacological assay,<sup>4</sup> the patient is given an amount calculated to be somewhat less than that required to render the urine sugar-free. If, however, we have an accurate idea of the sugar-burning power of this preparation by previous use in other patients, we may at once calculate the dose required to render the urine sugar-free for the twenty-four hours. Insulin is administered, according to the amount required, in one, two, or three doses, at or shortly before meals. Subcutaneous injection is the method of choice. Examination of the urine at short intervals enables one to determine approximately when the patient becomes sugar-free, and to adjust subsequent dosage to maintain this condition. Blood sugar estimations are useful in determining the level of blood sugar during treatment, and assist in spacing the time of administration of extract.

Special care is taken that the food consumed by each patient is appetizing in appearance, palatable to the taste, and well served. It is all weighed and checked according to a menu prepared by the dietitian attached to the clinic. Any unused food is weighed and the amount actually used determined. Records are kept of each article of food eaten by the patient, and in many instances this is kept constant for long periods as to amount, kind, and time of serving. Atwater's tables are used as a basis of calculation, together with certain later data available in the recent literature and from our own laboratories. Actual analyses of foods consumed are not made except for special purposes, but it is well known that, considering the other factors involved before assimilation of the foodstuffs, the calculation of the diet from published analyses is sufficiently accurate. Non-nutrient materials, such as bran cakes, agar jellies, thrice-boiled vegetables, mineral oil mayonnaise, broths, tea, coffee, etc., are made use of extensively to provide bulk and increase the palatability of the diet.

Twenty-four-hour specimens of urine are collected in the usual manner, and examined qualitatively and quantitatively for sugar, acetone, diacetic acid, and total nitrogen, as well as the usual routine tests for volume, specific gravity, albumin, and character of the sediment. Sugar is determined by Benedict's and Shaffer and Hartmann's methods; ketones (acetone and diacetic acid) by Rothera's and Gerhardt's tests and Van Slyke's methods. Total nitrogen is determined by a modification of the well-known Kjeldahl method. Blood sugar is estimated by the revised Folin Wu and Shaffer-Hartmann methods; blood ketones by Van Slyke's methods; carbon dioxide combining power of the blood by Van Slyke's method; alveolar air carbon dioxide by Marriott's method and a modification of Haldane's method, similar to Roth's. Basal metabolism and respiratory quotients are determined by the Douglas Haldane and Tissot-Haldane methods. Many of these chemical methods are not necessary for the actual clinical treatment of a diabetic patient but are useful for a metabolic study of the disease.

#### GENERAL CLINICAL RESULTS.

Up to the present time over fifty cases of diabetes mellitus have been treated with insulin, and some have been under treatment continuously for several months. Although the most striking results have been seen in children and young adults, all patients have been benefited by the treatment. Many of the patients have come to the hospital in a state of extreme under-nutrition, suffering from great weakness along with an indisposition to any physical activity. On the first or second day of treatment, if sufficient insulin is given, the urine becomes sugar-free, and on the second or third day ketone-free. These patients become conscious of increasing strength before the end of the first week. From a state which may be one of discouragement or of profound mental depression they become cheerful and interested. Hunger is replaced by appetite; the thirst is lessened. Oedema, which is common in these cases, disappears. Patients find they are less irritable, and state that they begin to sleep well. The expression improves; the skin becomes less harsh and dry; even the hair becomes softer; in fact, the patient loses that appearance which characterizes the diabetic. In ten days a very considerable amount of physical vigour is restored. Some patients have been able to return to work after a month of treatment. The patient's weight frequently increases, and this can readily be brought about by supplying food in excess of the calorie requirement and increased amounts of insulin.

\* Full details as to the calculation of diets will be published shortly by one of us (W. R. C.).

One patient, aged 16, who had lost 40 lb. during her three years of diabetes, gained 35 lb. in less than four months. Mild infections are favourably influenced; for example, the pain of a chronic pyorrhoea was relieved by treatment; it recurred when the injections were stopped, and was relieved again when they were continued. Simple catarrhal infections are no longer of serious import. During this time the urine can be kept sugar-free and ketone-free. The morning blood sugars are lower and may approach the normal level. Lipaemia was present in a few cases and disappeared with treatment.

The following case is reported briefly:

T. H. B., aged 25; glycosuria discovered November, 1920, when the patient was suffering from a series of boils. Weight at that time 160 lb. Has been under continuous dietetic supervision since onset. Glycosuria became much worse in November, 1921, when increase in diet was tried. Condition became progressively worse up to time of admission, September 18th, 1922. During ten days of preliminary observation his weight varied between 112½ and 116 lb. He was emaciated, weak, and depressed. He was given a diet of protein 36 grams, fat 140 grams, carbohydrate 41 grams. Average daily excretion of urine 4 litres; specific gravity 10.10 to 10.16; glucose 38 to 75 grams; ketones, varying from 0.3 to 1.7 grams; total nitrogen 8.5 to 12 grams; morning blood sugar 0.215 per cent. For two weeks following October 4th he was given three daily injections at meal time of 2 c.cm. of insulin. After the first day he remained sugar and ketone free. Urinary nitrogen was on the average 1.5 grams less than before treatment. Fasting blood sugar on the fourth day was 0.134 per cent. The restoration of strength was rapid and by the end of two weeks the patient was able to take daily walks of two and three miles. On October 26th he was discharged, and continued to receive 3 c.cm. of insulin a day. His diet was increased to—protein 36 grams, fat 140 grams, carbohydrate 61 grams. He is feeling well and strong. He states that he does his work as a bank clerk with ease, and is quite free from fatigue at the end of the day. He has remained sugar-free since discharge. On December 5th the examination of a twenty-four-hour specimen of urine gave—volume 2,380 c.cm., specific gravity 10.08, sugar absent, acetone absent. His weight was 125 lb.

#### GLYCOSURIA.

Probably the condition toward the alleviation of which most attention has been directed in the therapy of diabetes is the glycosuria. While regarding this symptom as being, in most cases, of not more than secondary importance, it is nevertheless one in which the efficiency of insulin may be most convincingly demonstrated.

We have encountered no cases of diabetes mellitus in which insulin, given in adequate amounts, did not make patients aglycosuric within a remarkably short time, in spite of the fact that they had been excreting large quantities of sugar for months while on a fixed diet, and even in spite of large increases (1,000 calories) in the various foodstuffs. Maintenance of a patient without glycosuria may be a more difficult proposition, and involves a good many factors which will be touched upon later. However, in conjunction with a reasonably well controlled diet on which, without insulin, the patient formerly excreted large quantities of sugar, this has been accomplished for long periods. The dosage of insulin required to effect this has naturally varied in different cases and with various preparations of the pancreatic extract, but as a rule is much less than is required initially to render the patient sugar-free. Certain cases indeed may, after a period of insulin treatment, recover such a degree of tolerance as no longer to require extract to maintain them on a basal diet. The treatment and final outcome of such patients is a most interesting subject for future investigation to determine. We are at present inclined to the opinion that the newly regained tolerance of these patients should be protected for a time by the use of small amounts of insulin. An illustration of some of these points occurs in the case of a man aged 57, who entered the hospital on November 10th, 1922. He was placed on a diet of protein 27 grams, fat 116 grams, and carbohydrate 34 grams, and containing 1,288 calories. He remained on this diet for nine days, during the last four of which the sugar excretion was 27 grams a day. On November 19th the diet was increased for certain reasons to 2,280 calories, and was composed of protein 60 grams, fat 200 grams, and carbohydrate 60 grams. Simultaneously the dose of a certain batch of insulin required to make him sugar-free on the increased diet was calculated and administered on the same day. The result was that the patient has been sugar-free continuously since that time on the same diet, though the dosage has gradually been reduced to half the original amount.

#### KETONURIA, ACIDOSIS, AND COMA.

In practically all patients accepted for treatment an additional problem has presented itself in the management of varying degrees of disturbed fat metabolism—ketonuria,

acidosis, and coma. Ketonuria, associated with glycosuria, clears up when sufficient carbohydrate is burned, and this result can sometimes be brought about by dietetic treatment alone. Under insulin treatment ketonuria is relieved in a striking manner, as in the following case: This patient, who on the previous day excreted 27.3 grams of sugar and 6.70 grams of ketones, was given one dose of 4 c.cm. of a certain preparation of insulin at 7 a.m. The urine was free of sugar at the end of two hours and of ketones in four hours. Sugar was again found in the urine at ten hours after the injection, ketones in eight hours. It is of interest to note here that ketones reappear in the urine two hours before sugar.

TABLE I.—Showing the Two-hourly Output of Sugar and Ketones in the Urine for the Twelve-hour Period following the Injection.

Time.	Volume, c.cm.	Sugar.		Ketones.	
		Per cent.	Grams.	Mg. per litre.	Mg. per 2 hrs.
7-9	40	0.75	0.3	1737	70
9-11	250	0	0	262	65
11-1	520	0	0	0	0
1-3	460	0	0	0	0
3-5	470	0	0	213	100
5-7	240	0.43	1.16	491	115

Cases of severe acidosis show the same prompt reaction to insulin treatment. Ketones disappear from the urine and blood, the normal alkali reserve of the blood is re-established, and the signs and subjective symptoms of the condition completely disappear.

To those who have previously striven, practically unrewarded, with cases of diabetic coma, one of the most interesting and valuable properties of insulin is its effect upon this condition, the mechanism of which we believe will throw an entirely new light on the intermediary metabolism of the foodstuffs. We have had an opportunity of treating 10 cases of complete coma (stage of complete anaesthesia) as well as other cases of coma imminens.

Of the 10 cases of complete coma treated 4 died. The first case of coma was admitted to hospital in February, 1922, and died in April. This case came into the hospital in a state of severe acidosis, markedly emaciated and dehydrated, with a high D/N ratio. Owing to the difficulty in the production of insulin at that time many of the preparations lacked potency and satisfactory treatment was impossible. The patient was treated at intervals with insulin. The acidosis was improved, to return when treatment was discontinued. The case gradually became worse and went into coma; was brought out by large doses of a weak extract; lapsed again into unconsciousness and died when the supply of extract was exhausted. One other fatal case was effectually brought out of coma but died of pneumonia. In the other two cases, one died with sloughing gangrene of the foot, and the other of complete vasomotor failure. In both these cases coma was relieved by insulin treatment. At the time of death the urine of these patients was free of sugar and ketones; the blood sugar and blood ketones were normal, and glycogen was found in the liver and muscles *post mortem*.

The remaining six cases of coma treated are all living. One has recovered and is now aglycosuric without insulin on a diet about double the basal requirement. The other five patients have remained free of symptoms and the urine free of sugar and ketones under dietetic treatment and the daily administration of insulin.

We are not prepared, at present, to lay down definite rules for the management of diabetics in coma, for we believe that with greater opportunities for study more satisfactory methods may be devised for treating this as well as other problems in relation to the disease. The use of large amounts of fluids by mouth, by the rectum, interstitially, or intravenously, seems very desirable. Rest, warmth, purgation, and stimulation in suitable amounts seem indicated. Sodium carbonate or bicarbonate presents difficulties in arranging proper dosage and undoubtedly kills when used in excess. There is some evidence of the usefulness of the intravenous injection of glucose as a diuretic in the earlier stages of coma. The fact remains, however, that in the past four years no case entering our wards in advanced diabetic coma has recovered by any of these methods. Though we are aware of a few isolated instances of such having taken place in other hospitals, we

believe the opinion is commonly held that such cases are practically hopeless. Insulin treatment may now be said to constitute an important step in the therapy of this condition. Insulin is administered to these patients either subcutaneously, or intravenously followed by subcutaneous injections. The dose employed has been usually, though not always, far in excess of the requirement, and the danger of a hypoglycaemic reaction is guarded against by sufficient glucose given at the same time. No attention need be paid to the glycosuria at this time, as the object is to correct the disordered fat metabolism and decrease ketone production. The glucose is necessarily given intravenously in advanced coma, and perhaps it is not amiss to warn against the danger of using any but the purest form of glucose and against sterilization at unnecessarily high pressures.

The first evidence of improvement is in the rise of alveolar  $\text{CO}_2$ , but the difficulties of getting satisfactory samples of alveolar air from comatose patients leave something to be desired in the way of constancy of results, and so clinical improvement usually is noted first, and consists in movements, fluttering of eyelids, etc., response to painful stimuli, etc. At the same time, however, there is reduction of the total ketones in the blood, though this information is usually received too late to be of service. The alkali reserve, as estimated by Van Slyke's technique, is more rapidly determined, and may be used to confirm the clinical impression. It tends to rise toward normal a little later, in our experience, than the reduction in blood ketone bodies, and distinctly later than pronounced clinical signs of improvement.

Probably a considerable number of us have been formerly misled by clinical evidence of apparent improvement in the patient which was not confirmed by laboratory data, and which we subsequently found to be unreliable. But, as well as strengthening our position from a clinical standpoint, the laboratory data also provide definite indications as to the necessity of administering further amounts of insulin or glucose. In the presence of a decided lowering of blood sugar the latter is desirable; while inadequacy of insulin dosage is indicated by failure of the alkali reserve to increase. When laboratory facilities are unavailable, a great deal of valuable information may be obtained by frequent examinations of the urine. Disappearance of sugar from the urine is an indication for the administration of more glucose or possibly the use of epinephrin; while reduction or disappearance of the ketones is a most favourable sign.

#### REACTIONS AND HYPOGLYCAEMIA.

Toxic reactions may follow the injection of an extract of any animal tissue, owing to its content of protein and split protein products. These reactions have been especially severe in the experience of investigators with pancreatic extracts, and have been the chief obstacle to their introduction for clinical use. Some reactions of this type were produced by injections of the extract first used by us. The present product, however, is practically protein-free, so that, with the exception of urticarial eruptions in one, or possibly two, sensitive patients, these occurrences are no longer met with. Insulin administration may be followed by a reaction of another kind, which is the result of the fall in blood sugar (hypoglycaemia). When a single injection is given to a patient there is a rapid fall of blood sugar which reaches a low point in two to eight hours, and tends to return to the original level in twelve to twenty-four. Such a result is recorded in Table II.

TABLE II.—Showing the Fall in Blood Sugar following a Single Subcutaneous Injection of Insulin, given at 7 a.m.  
(The urine was free of sugar from 9 a.m. to 3 p.m.)

Time.	Blood sugar percentage.
7 a.m. ... ..	0.278
9.30 " ... ..	0.174
11 " ... ..	0.105
12.30 p.m. ... ..	0.073
3 " ... ..	0.127
6 " ... ..	0.168

While the extent of this fall is dependent in a measure upon the amount of insulin and upon the initial blood sugar level, it cannot be predicted with any great degree of accuracy in an individual patient. In giving a dose, therefore, to render the patient sugar-free it sometimes happens that the blood sugar falls well below the normal level, and this sudden hypoglycaemia is accompanied by a characteristic train of symptoms. When the blood sugar percentage falls to 0.07 per cent. under the influence of insulin, the patient becomes aware of it. He may first complain of hunger, or more often

a sense of weakness or fatigue, and, especially if it is his first reaction, he is conscious of some anxiety or of what he calls nervousness, or he may even show the signs of a definite neurosis with loss of emotional control, such as crying spells. Almost constantly present is a feeling of tremulousness; actual tremor is rarely seen. The patient may also have some inco-ordination for fine movements. Vasomotor phenomena are common: pallor or flushing, sometimes one after the other; a sense of heat or chilliness; almost always a profuse sweat. The severity of these symptoms increases with the hypoglycaemia, and the lowering of the blood sugar near to 0.05 per cent. produces very acute distress or even mental disturbances, such as confusion and disorientation. A blood sugar of 0.032 per cent. resulted in a state of coma with hypotonia and loss of deep reflexes. One patient while asleep passed into a low muttering delirium as the blood sugar fell to 0.052 per cent. This was followed by uncontrollable hunger. A blood sugar of 0.053 per cent. in another case was accompanied by weakness, crying, and extreme anxiety. One patient was quite irrational while his blood sugar was around 0.06 per cent. On another occasion he became deaf and had difficulty in articulation. This difficulty in articulation has been seen several times. Others have had only a vague feeling of uncertainty which would have passed unnoticed had they not experienced a previous reaction. In such cases the blood sugar is usually about 0.075 per cent.

These reactions can be relieved by food administration; 50 to 100 c.cm. of orange juice has an almost immediate effect in clearing up the symptoms. A better result is obtained with 5 to 25 grams of glucose given with orange or lemon juice. When a patient is unconscious 1 c.cm. of epinephrin (1 in 1,000 solution) should be given intramuscularly, followed by glucose by the mouth. If the patient is not well enough in a few minutes to swallow glucose, it may be given subcutaneously or intravenously. Special nursing precautions should be taken for the detection of reactions when insulin treatment is first started, when a new preparation is given, and when insulin is administered late in the day, as the reaction may occur during sleep. As yet pharmacological assay of the potency of insulin has not been satisfactory, and to this may be attributed the occasional reactions seen when new preparations are used. However, once a patient has had a reaction he is quick to recognize the onset of the next one, and means may be taken to relieve it. Up to the present time no serious mishap has occurred as a result of these hypoglycaemic reactions, but while this is so it is felt that hypoglycaemia constitutes a real source of danger.

#### GENERAL DISCUSSION OF RESULTS.

The dosage of insulin is a very important factor in the successful treatment of a patient; on the one hand, we have to fear hypoglycaemic reactions, and, on the other, we know that glycosuria will result when the blood sugar rises above the patient's threshold level for excretion of sugar. It is, therefore, not always easy to adjust the conditions so that there is sufficient insulin present to nullify the post-prandial hyperglycaemia, and yet insufficient to produce a dangerous lowering of the blood sugar. We know, however, that the effect of insulin on blood sugar is not exerted immediately after subcutaneous injection, and therefore we space the injections so that their effect is occurring during the period of assimilation of carbohydrates. This usually means injecting the insulin at, or shortly before, the meal, but instances occur—possibly due to delayed, or too rapid, absorption of sugar into the blood stream, the use of meals containing too much high carbohydrate food, etc.—in which glycosuria occurs at one time and reaction at another. These, fortunately, are not common, but serve to emphasize the necessity for careful observation of the patient for a period in a hospital before discharging him to the care of his private physician. Further, the initial symptoms of reaction are so specific as to leave no doubt in the mind of anyone who has seen them, and the remedy is, fortunately, easy to apply before there is any real danger.

At the end of the preliminary period of observation on a fixed diet the majority of cases of severe diabetes excrete a fairly constant amount of sugar, and this information is most valuable in determining the actual amount of insulin to be employed in treatment. In certain cases, possibly owing to daily fluctuation in tolerance for carbohydrates, the daily excretion of sugar varies and it is impossible to determine the initial dose of insulin. In these cases it is advisable to begin with a moderate dose, gradually increasing it until the

desired effect is obtained. The amount of insulin used will depend not only on the carbohydrate tolerance of the patient, but on the height and fixity of the blood sugar level.

Whether we shall in the future permit patients to have higher blood sugar levels than at present seems advisable is a point on which there is conflicting evidence. At present we are inclined to the belief that more successful results are obtained with regard to the general well-being of the patient, clearing up of minor and even major infections, etc., if a normal blood sugar level is aimed at. Owing to the short duration of the effect of insulin it might seem desirable to ingest the carbohydrates at one particular meal and give the extract in relation to this meal, thus avoiding the number of injections—two to three daily sometimes necessary in the severer cases. This, however, is not the case, as the carbohydrate is apparently stored and burned under the influence of the insulin, and during this period the patient feels like a healthy, normal person, and later, when only fat and some protein is available for burning, he gets a mild ketosis and experiences lassitude or fatigue. In our view a prolongation of the period of action is most desirable, and whether this is to be obtained by slowing the rate of absorption or by more frequent injection is a matter for further study.

After these patients are freed from glycosuria and ketosis and are permitted to use an adequate basal ration they usually feel so well that they demand increased food to satisfy their desire for exercise. In this case we are less particular about spreading the carbohydrate intake throughout the day and usually prescribe an increased amount of carbohydrate with three to four times as much fat at one or possibly two meals, and a corresponding amount of insulin. The same thing may be accomplished by raising the diet instead of decreasing the initial dose of insulin. As the protein is not as efficient as carbohydrate in preventing disordered fat metabolism, the amount of fat which can be given with protein is much less than with carbohydrate. Owing to the high caloric value of fat it seems desirable to raise first the carbohydrate in the diet. When increase in calories is not so urgently required, then protein may be used and fat added in the proportion of 10 grams of fat to each 8 grams of additional protein.

In severe diabetics and comatose patients the alterations in metabolism under the influence of insulin are most interesting. They furnish material for a considerable amount of investigation which we hope to report upon later. The study of the respiratory quotient reveals positive evidence of the utilization of carbohydrates. Patients with any considerable carbohydrate tolerance may be expected to produce a certain amount of insulin themselves. This may be mobilized under suitable stimuli, and the initial rise in the respiratory quotient sometimes seen is probably due to this factor. The specific effect following the administration of insulin is almost coincident with the attainment of normal blood sugar levels. Demonstration of the effect of pancreatic extracts in raising the respiratory quotient can best be made on the most severe cases of diabetes mellitus.

Other factors which we must decide in the patient's interests are his most suitable weight and condition of nutrition and the means which shall be employed to attain them, and also to what extent work shall be allowed. Following the principle of low maintenance diets in treatment it seems unwise to allow increases in weight in stout patients, or even marked increases in the emaciated. In the former, reduction of the patient's weight by using insufficient fat in the diet is recommended; in the latter it is felt that some increase in the weight is desirable on account of the associated improvement in the general condition of the patient, his resistance to infection, etc., even though an increased amount of insulin is required. Work, involving as it does the increased use of foods and consequent drain on the supply of insulin, is not to be regarded as desirable when pushed to excess, and patients are accordingly advised to moderate their usual activities.

Diabetics are perhaps more subject to infections and gangrene than any other class of patients. In such cases a distressingly high mortality has been observed. Without doubt the more recent dietetic treatment has removed many of the terrors of operation, such as coma, and has even aided in the more rapid clearing up of infections for the less severe degrees of the disease. However, many patients lose a great deal of their carbohydrate tolerance when infection is added to their diabetic condition. And further, the infections are more prone to occur in the more severe cases who do not respond favourably to dietetic treatment. For both types of

patients insulin furnishes most valuable assistance in treatment in that it keeps the blood sugar normal—an important consideration in the treatment of infection—enables the patient to utilize carbohydrates, and, in consequence, prevents acidosis and removes the danger of post-operative coma. It seems clear that necessary surgical procedures may be undertaken in properly treated cases with practically no more risk than in the normal.

Attention must be paid to various other influences in the treatment of diabetic patients. Symptomatic treatment for minor complications, such as constipation, insomnia, etc., must be carried out. Psychic factors, such as fear, anxiety, and worry, are well known to produce hyperglycaemia and glycosuria. The effect of insulin is so specific that these need not be considered as influencing the results of treatment, but in this, as in all other diseases, the best results in treatment can be obtained with happy, contented patients.

#### SUMMARY.

The following is a summary of the results of our investigation:

1. Under treatment with insulin in patients who are not otherwise amenable to treatment:

- (a) Glycosuria is abolished;
- (b) Ketones disappear from the urine and the blood;
- (c) Blood sugar is markedly reduced and maintained at normal levels;
- (d) The alkali reserve and alveolar carbon dioxide of patients in acidosis and coma return to normal;
- (e) The respiratory quotient shows evidence of increased utilization of carbohydrates;
- (f) The cardinal symptoms of diabetes mellitus are relieved and the patients show well-marked clinical improvement.

2. Insulin is a specific in the treatment of diabetic coma.

3. Certain procedures are suggested as a guide in the administration of insulin.

4. Hypoglycaemic reactions in man have been studied and described.

5. Hypoglycaemic reactions following insulin are relieved by the administration of carbohydrates and also by the injection of epinephrin.

To Dr. Duncan Graham, professor of medicine, we desire to express our sincere thanks for his interest in directing and supervising the investigation throughout its course.

## ON A POSSIBLE MODE OF CAUSATION OF DIABETES MELLITUS.

BY

L. B. WINTER AND W. SMITH.

(From the Biochemical Laboratory, Cambridge.)

In a paper, now in the press,<sup>1</sup> we show that the normal blood sugar in man and animals has a lower rotatory power than would be given by the  $\alpha$ - $\beta$  equilibrium form of glucose as deduced from the copper reduction value. The sugar gives an osazone with the same crystalline form and melting point as that of glucosazone. The instability of the sugar is shown by its transient rotatory power, the curve of polarimeter readings reaching the copper reduction value in three to four days in acid solution. The sugar at first decolorizes potassium permanganate more rapidly than a solution of  $\alpha$ - $\beta$  glucose in similar concentration. This distinction no longer obtains when the polarimeter reading corresponds with that of  $\alpha$ - $\beta$  glucose. These facts, in conjunction with the work of Hewitt and Pryde<sup>2</sup> on sugar solutions introduced into the intestine, suggest that normal blood sugar is  $\gamma$  glucose. That ingested glucose or fructose is rapidly converted into normal blood sugar was shown by feeding experiments on normal persons. After 100 to 150 grams of glucose or fructose no alteration in the nature of the blood sugar could be detected.

In cases of diabetes mellitus we show that this sugar is not present in amounts capable of detection by the method employed. The polarimeter reading in these cases is initially greater than the copper reduction value, and the

curve gradually falls until the copper value is reached. This suggests that besides  $\alpha$ - $\beta$  glucose, disaccharides or other substances with a polarimeter: copper reduction ratio greater than that of  $\alpha$ - $\beta$  glucose are present in the blood of diabetic persons. We suggest that  $\alpha$ - $\beta$  glucose cannot be directly stored or utilized, but that an enzyme is responsible for the conversion of  $\alpha$ - $\beta$  glucose into  $\gamma$  glucose. We picture the change:

The absence or inactivation of this enzyme is suggested as the direct cause of diabetes mellitus.

Macleod and his co-workers<sup>2</sup> have recently shown that injection of "insulin" into depancreatized dogs causes a decrease in the blood sugar. Determinations of the respiratory quotient showed that sugar was being utilized as long as the administration of insulin was maintained. Similar results were obtained by the injection of insulin into persons suffering from diabetes mellitus. We suggest that the effect of the insulin is to activate the enzyme responsible for the conversion of  $\alpha$ - $\beta$  glucose  $\rightarrow$   $\gamma$  glucose. If this view be correct, examination of the blood sugar of diabetics after injection of insulin should show that the nature of the sugar approximates to that of normal persons.

We have investigated the action of tissue extracts on the rotatory powers of glucose and fructose. We have confirmed the observations of Hewitt and Pryde<sup>3</sup> that extracts of the intestinal mucous membrane are inactive. The liver would appear to contain the enzyme. That another factor is concerned is shown by the fact that the enzyme is almost inactive in the absence of an extract of pancreas. The extracts of pancreas which we have recently used are preparations of "insulin" obtained by Collip's method.<sup>4</sup> Similar activation of the enzyme is obtained.

Solutions of glucose or fructose when incubated at 37° C. with very small amounts of insulin and liver extract in a jacketed polarimeter tube have their rotations altered in a downward and upward direction respectively. In view of the fact that our insulin preparations invariably contain phosphorus, it is noteworthy that addition of phosphate accelerates the reaction to a degree not obtained by the use of other salts. Phosphate buffers have therefore been employed. Boiled liver extract is inactive, whereas insulin would appear to be thermostable in this respect. Our insulin preparations were tested for activity on rabbits.

The degree of alteration in rotatory power may be seen from the following examples:

Glucose.		Fructose.	
First reading ...	1.70° R.	First reading ...	177.92°
Lowest reading ...	1.47° R.	Highest reading ...	178.30°
The solutions contained 15 c.cm. of an arbitrary glucose or fructose solution, 2 c.cm. phosphate buffer, 1 c.cm. 0.1 M. KCl, 1 c.cm. weak insulin solution, 0.3 c.cm. liver extract.			
Without phosphate—			
Glucose.		Fructose.	
First reading ...	1.32° R.	First reading ...	178.60°
Lowest reading ...	1.30° R.	Highest reading ...	178.61°

The enzyme would appear to be slowly inactivated under these conditions. The unstable nature of the sugar formed is shown by the fact that after the maximum change has occurred the rotation tends to revert to the original value. Our experiments with the enzyme *in vitro* do not show a ratio copper reducing: polarimeter value equal to those observed in the case of blood sugar. It is difficult to convert any considerable amount of the sugar in our solutions into the reactive form, as this is not removed from the sphere of action. A stage would appear to be soon reached at which the reverse process attains a velocity equal to that of the original one.

The copper reducing power of the sugar solution at the beginning and end of the reaction is unaltered. The reaction is therefore different from that described by Levene and Mayer<sup>5</sup> in connexion with muscle and pancreas extracts, in which the copper reducing power was lowered.

This method would seem to lend itself to the further purification of insulin. We have already found that the final product obtained by Collip's method is capable of being divided into two fractions, which differ markedly in their nature and activity as tested by the above method and on rabbits.

## THE VITAMIN CONTENT OF CERTAIN PROPRIETARY PREPARATIONS.

BY

KATHARINE H. COWARD, M.Sc.,

AND

A. J. CLARK, M.C., M.D., F.R.C.P.,

PROFESSOR OF PHARMACOLOGY, UNIVERSITY OF LONDON.

(From the Institute of Medical Sciences, University College, London.)

At the request of the BRITISH MEDICAL JOURNAL the writers have examined the vitamin content of certain of the best known of those proprietary preparations which are advertised in the medical press as containing vitamins. The following preparations were tested:

*Metagen* (Messrs. Parke, Davis, and Co.). The advertisements state that this is guaranteed to contain the three principal vitamins, and that it is "a concentrated product for therapeutic administration."

*Maltoline* (the Maltine Manufacturing Co., Ltd.). The advertisements state: "Maltoline is therefore rich in three well-known vitamins, and is recommended as a nutritive to those who are unable to take or digest cod-liver oil"; and also that "Maltoline . . . satisfactorily takes the place of cod-liver oil."

*Roboleine* (Messrs. Oppenheimer, Son, and Co., Ltd.). The advertisements state: "The 'A.B.C.' of Diet. Because it is very rich in the vitamins 'A,' 'B,' and 'C' there is no tonic food more serviceable in wasting diseases"; and the statement is also made that it "supersedes cod-liver oil."

*Virol* (Virol, Ltd.). The advertisements state that one of the "essential points in the diet of growth" is that "the food must contain those food accessory substances known as vitamins, but the presence of vitamins is not sufficient in itself," and that "Virol as it reaches the public contains the vitamins."

*Vitmar* (Messrs. Callard and Co.). The advertisements state: "Biological tests prove that vitmar contains vitamins in abundance."

*Mellin's Food* (Mellin's Food, Ltd.). The advertisements state: "Vitamins. Those elusive principles of food which are essential to nutrition are present in Mellin's food when mixed for use as directed according to the age of the infant."

The specimens of these foods tested were all bought in the open market. Most of them claim to contain all three vitamins. Vitamins A and B are rapidly destroyed by certain chemical processes, and therefore their concentration or purification is a matter of extreme difficulty, but it is not difficult to prepare them in an unconcentrated form, in which they will keep for a prolonged period. Vitamin C is much more unstable; so far as we can ascertain it has not been concentrated, and it is difficult even to preserve it in a crude form. Dried orange and lemon juice are indeed the only known preparations in which this vitamin can be preserved for prolonged periods.

We have therefore only tested the above preparations for the presence of vitamins A and B, and have not tested for the presence of vitamin C, for it is reasonable to assume that any methods for the concentration or preservation of vitamins which fail in the case of vitamins A and B will be even less successful in the case of vitamin C.

The presence of vitamin A was determined as follows: Young rats (weight about 50 grams) were fed upon a diet which was free from vitamin A, but otherwise adequate. The rats consumed from 16 to 20 grams of food (moist weight) daily. On this diet they soon ceased to grow, and then a known amount of the substance to be tested was given to the rat before its basal diet each morning, or added to a small amount of the diet which was consumed before the rest of the basal diet was given. The minimal amount of the substance which contained sufficient vitamin A to produce growth in young rats was thus determined.

The presence of vitamin B was also determined by experiments upon rats. In this case young rats were fed upon a diet free from vitamin B but otherwise adequate. This diet soon caused arrest of growth, and the vitamin B content of the proprietary preparations was determined by finding the minimal quantity of the various preparations required to produce growth.

The course of the experiments made with metagen is shown in the accompanying figure. The curves marked A I show the effect of feeding 0.15 gram of metagen daily to rats on a diet devoid of vitamin A; this produced growth in one rat and failed to do so in two others; this result is termed "doubtful

TABLE I.—Vitamin Content of Proprietary Preparations as determined by their Power to Produce Normal Growth in Young Rats (weight about 100 grams) living on a Diet free from the Vitamin under consideration.

(D)=Doubtful growth. (Ir)=Irregular growth. (N)=No growth.

growth" in Table I. In the figure, A II shows the effect of 0.3 gram of metagen on rats on a similar diet; regular growth resulted in all three cases; this is termed "normal growth." B I shows the effect of feeding 0.08 gram of metagen daily to

rats on a diet devoid of vitamin B; no growth resulted in three cases. B II shows the effect of 0.15 gram of metagen; this produced regular growth in one case and defective growth in two cases. This result is termed "irregular growth" in Table I. B III shows that 0.3 gram of metagen produced regular growth in three cases, and this is termed "normal growth."

The results obtained with the various preparations are summarized in Table I; this table also shows, for the sake of comparison, the vitamin content of certain common foods. The doses given in the table are as accurate as can be obtained in biological tests of this nature, but can only be considered as approximately correct.

The results recorded in Table I show that the preparations tested contained vitamins A and B, except maltoline, in which case the tests failed to show the presence of vitamin A in the quantities tested. A dose of 1 gram of maltoline, which is about 8 per cent. of the total diet (dry weight) of a rat, did not contain an active amount of vitamin A, and it seemed unnecessary to repeat the test on a higher dosage. A comparison between the vitamin content of the proprietary preparations and the vitamin content of those ordinary foods which are rich in vitamins shows that the former contain less vitamins than the latter. The vitamin A content of the proprietary foods was in all cases less than that of butter obtained from grass-fed cows, and less than one-hundredth that of active specimens of cod-liver oil. The vitamin B content of the proprietary foods was in all cases less than that of wheat germ or of yeast. The vitamin value of these foods as compared with that of milk from grass-fed cows is shown in Table II.

Mellin's food is not included in Table II as it is not given alone but is mixed with milk; if the food is mixed with milk in the proportion of a teaspoonful of food to two tablespoonfuls of milk the vitamin content (A and B) of the food will raise the vitamin content of the milk. The vitamin content of Mellin's food may therefore be sufficient to be of value in cases where an infant is being fed on milk which has a low vitamin content. As regards the other preparations, none of them can be said to contain a rich, abundant, or concentrated supply of vitamins. None of them can be considered to be a substitute for cod-liver oil as a source of Vitamin A, for in no case does the total daily adult dose of the proprietary food contain as much as one-tenth of the vitamin A

TABLE II.—The Relative Value of Proprietary Foods and Milk as Sources of Vitamins.

Proprietary Food.	Adult Dose.	Approximate Weight of Total Daily Adult Dose.	Amount of milk which provides approximately the same quantity of Vitamin as is contained in the daily adult dose of the proprietary foods.	
			Vitamin A.	Vitamin B.

content of a teaspoonful of cod-liver oil. The present paper is of course solely concerned with the vitamin content of these preparations, and no opinion is expressed concerning their merits in any other respect. Whilst these experiments were in progress two papers appeared in America describing similar investigations.

Hess, Moore, and Calvin<sup>2</sup> investigated the content in vitamin B and C of metagen and vitamin (mastin). They concluded that "metagen as obtained on the open market contains no demonstrable amount of antiscorbutic substance (vitamin C), as shown by experiments on guinea-pigs." They also found that metagen contained less vitamin B than commercial yeast, as shown by its power to protect pigeons from polyneuritis.

McCullum and Simmonds<sup>3</sup> measured the vitamin B content of six proprietary vitamin preparations advertised in the

United States; one preparation (Yeast Vitamin Harris) was found to contain a considerable quantity of vitamin B, but the others contained little or none of this vitamin.

Dell<sup>4</sup> found that half a capsule of metagen daily failed to maintain life in a guinea-pig on a scorbutic diet, although a dose of 0.5 c.c. orange juice daily had previously maintained the animal in normal health. This result agrees with the conclusions of Hess, Moore, and Calvin.

The experiments recorded in the present paper show that in none of the cases examined have the manufacturers succeeded in concentrating vitamins on the commercial scale. This result was only to be expected, for the concentration of the two more stable vitamins (A and B) is a process of the greatest difficulty even on a laboratory scale, and in the case of the successful attempts the final yield of purified vitamin only represents a minute fraction of the total quantity of vitamins present in the raw material.

Our experiments confirm what other workers on vitamins have emphasized—namely, that under normal conditions of life an adequate supply of vitamins can be easily ensured by including in the diet a suitable amount of "protective foods," such as milk, butter, green vegetables, and fruit, and that no advantage is to be gained by trying to obtain these substances in the form of drugs.

Since the above article was written Bailey<sup>5</sup> has reported that he tested the activity of more than twenty commercial vitamin preparations, and found that only in two or three was the vitamin B content higher than that of dry brewer's yeast; in several the vitamin B content was negligible.

Note.—The expenses of this research were defrayed by a grant from the British Medical Association.

## APITUITARISM AND THE ANENCEPHALIC SYNDROME.

BY

D. L. BARLOW, M.B., B.S. ADELAIDE,

HONORARY CLINICAL PATHOLOGIST, ADELAIDE HOSPITAL; PATHOLOGIST AND BACTERIOLOGIST, ADELAIDE CHILDREN'S HOSPITAL.

The subject of apituitarism and the anencephalic syndrome was brought to my notice by a leading article in the *BRITISH MEDICAL JOURNAL* of November 27th, 1920, which drew attention to the work of F. J. Browne, published in the *Edinburgh Medical Journal* (vol. xxv, page 296).

As a result of investigations in five instances of anencephalic foetus, Browne concluded that certain characteristic features of the condition were due to a failure of development or to destruction of the pituitary gland. In particular he directed attention to the large amount of subcutaneous fat, the hypoplasia of the thymus, suprarenal, and genital glands, and the shortness of the limb bones, and stated that these facts showed that the mother's internal secretions play little part in the metabolism of the foetus, which relied on its own glands. He also considered that the facts established formed an important confirmation of the functions of the pituitary glands.

I have examined four anencephalic foetuses, three preserved in the museum of the Adelaide Hospital, and one recent specimen placed at my disposal by Professor Wood Jones. In each of the four instances the anterior (pharyngeal) portion of the gland was found without much difficulty in its usual situation and resting on the body of the sphenoid. In none of the cases was any real attempt at the formation of a sella turcica apparent, though the gland was of a size approximating that in a normal full-time foetus.

In one instance a process of apparently neuroglial tissue, probably representing the pars nervosa, was found; and it is

noteworthy that this was the only one examined comparatively soon after delivery. In all, microscopic sections displayed a structure corresponding with the epithelial segment of the pituitary body—namely, strands of polygonal cells with somewhat granular protoplasm and rounded nuclei, separated by a loose connective tissue, in which were abundant thin-walled vessels. From the position and structure of these glands I have no doubt that they represent the epithelial portions of the pituitary.

[Dr. Barlow sent with his manuscript a microscopic section, which we have submitted to Professor S. G. Shattock, F.R.S., who confirms the view expressed, and has superintended the accompanying drawing (by Mr. J. Ford) of the author's specimen.]

ars anterior of  
foetus, exhibi-  
Thered blood  
are stained of  
1/5 objective.

cerebrum, cerebellum, or pons was present excepting loose vascular connective tissue. The eyes were moderately prominent and the orbital plates much foreshortened. No sella turcica was present, but resting on the body of the sphenoid was a small rounded moderately dark body. No stalk was apparent. Microscopic section showed glandular cells in strands separated by loose connective tissue containing many thin-walled blood vessels.

2. Male anencephalic foetus, normal full-time size. The eyes were prominent and orbital plates foreshortened. There was no

My observations make it appear probable that the gland has been in reality present in cases examined by others, but has not been distinguished from the vascular connective tissue covering the base of the skull.

As a result of the discovery of the anterior segment of the pituitary gland in four successive typical examples of the anencephalic syndrome, it may be concluded that the other features of the condition are certainly not due to apituitarism, and that any conception of the functions of the gland based on such an assumption is erroneous.

Details of the specimens examined are as follows:

1. Male, about the size of an average full-time foetus. Nothing representing the anterior segment of the pituitary gland in four successive typical examples of the anencephalic syndrome, it may be concluded that the other features of the condition are certainly not due to apituitarism, and that any conception of the functions of the gland based on such an assumption is erroneous.

trace of a sella turcica, but a glandular body was found resting upon the body of the sphenoid as in 1; the size was approximately the same and the structure similar. No trace of the brain stem above the level of the medulla was present.

3. Small male anencephalic foetus about two-thirds the size of a normal full-time foetus. The eyes were very prominent, especially the right. The gland in this case was smaller; it corresponded in structure with that of 1 and 2, and its location was similar.

4. Male anencephalic foetus about the size of a normal full-time foetus. The eyes were prominent. There was a moderate amount of adipose tissue. The base of the skull was covered, as normally, with loose vascular connective tissue with a very thin superficial covering of neuroglial nervous tissue. Amongst the dark vascular tissue a tongue-like projection of neuroglial tissue, somewhat irregular in outline, projected from the superficial neuroglial layer in the direction of the glandular portion of the pituitary body, which was found in the usual position. The glandular portion showed the same structure on microscopic section as in the previous cases.

## PURPURA TREATED BY INJECTION OF HUMAN BLOOD.

BY  
MONTAGUE DIXON, M.D., B.Sc.LOND.,  
MELTON MOWBRAY.

THE unfailing success of the treatment of haemorrhage of the newborn by injection of parental blood suggested to me the use of the same method in purpura. The result has been most encouraging, and I venture to hope that in this method of treatment, applied at the very onset of the disease, we have a sure way of curing it.

I have injected 2 to 5 c.cm. of blood, taken from the brachial cephalic vein, into the gluteal muscles. Clotting is prevented by sterilizing the syringe and needle in a solution of magnesium sulphate. I have used the method in four cases, with gratifying results in all, and in the very early cases (III and IV) with complete abortion of the attack.

### CASE I.

S., a boy aged 4 years, had been ill some five weeks before I saw him, so that the improvement was not so startling as in the other cases, which I got early; but the parents maintain with confidence that the injections saved the child's life, and that is also my opinion.

He was taken with pains in the legs early in February, 1920, whilst out walking, so that on two successive days he had to be carried home. After his bath his legs were tender, and he cried when they were rubbed with the towel to dry them. Purpuric spots appeared, and there was swelling of the face. A fortnight later the child had severe colicky pains in the abdomen, especially at night, and melaena was noticed. Absolute anorexia supervened, leading to acidosis, which was relieved by rectal injections of Mellin's food. A daily wash out of the colon was prescribed as the stools were so foul. Once a bowel cast of mucus was passed, and this was followed by complete relief of the colic for four days. There was often melaena and frequently haematuria. Purpuric spots appeared regularly. The child was very ill, wasting, and listless.

On March 14th I gave the first injection of blood (paternal). A definite amelioration of the child's condition resulted. On March 27th the second injection of blood (maternal) was given. This again led to benefit, and by the end of April the patient was convalescent. In June all symptoms had disappeared, except that some purpuric spots appeared on the legs if the child did not take an afternoon rest.

### CASE II.

C., a man aged 60 I had watched in the past in many attacks of subacute purpura, with visceral pains, which had yielded to horse serum administered by the mouth. On March 19th, 1922, he had had one week's epistaxis, and there was a subcutaneous haemorrhage on the right calf. One injection of blood (the son-in-law) resulted in cure.

On August 4th there was a subcutaneous haemorrhage on the leg, and a subconjunctival one too; the injection had the same good effect.

### CASE III.

W., a girl aged 3, was brought to me on March 31st, 1922, by her mother with an extensive outbreak of purpuric spots on the buttocks, thighs, and legs. I gave maternal blood at once. On April 3rd a few spots appeared over the biceps of the arm. On April 7th there were a few on one leg and slight epistaxis. After this there was no further trouble.

### CASE IV.

K. P., a girl aged 6, was brought to the surgery on September 6th, 1922, with purpuric spots on buttocks and legs (which had been present three days) and swelling of the right knee. There were pains in the knee and legs, and the temperature was 101°. Maternal blood was given at once. On September 8th there was a small haemorrhage on the left forearm. On September 9th paternal blood was administered. There were no further symptoms.

## FURTHER NOTES ON TREATMENT OF EPILEPSY.

BY  
JOHN MCCARTNEY, L.R.C.P. AND S.E.,  
ASSISTANT MEDICAL OFFICER, LANARK DISTRICT ASYLUM,  
HARTWOOD.

IN the BRITISH MEDICAL JOURNAL of October 9th, 1920, and again of October 1st, 1921, I published articles giving the results of the treatment of epilepsy by potassium bromide and borax after four and twelve months respectively. At the end of the second year's treatment I append the following notes on eighteen male cases, and I have chosen these because their history as regards fits, before treatment, is definitely known. I had hoped to quote twenty cases, but two died before the second year of treatment was completed—one of pulmonary tuberculosis and the other of cerebral haemorrhage. At *post-mortem* examination the first showed an interesting condition, which, I think, indicated that the epilepsy was traumatic. In the frontal region of the skull there was evidence of an old fracture, with a lump of callus on the inner table, which, pressing on the brain, had caused a cup-like depression in the latter. This patient had shown a reduction of 64 per cent. in the number of fits with one year's treatment. The second case was aged 72, and his record of fits was from 36 to 0 with one year's treatment.

I have divided the cases into two groups, according to the duration of their epilepsy.

Group I includes fifteen patients who have suffered from epilepsy for over twenty years, the shortest period being twenty-one years and the longest thirty-five years. Their ages range from 26 to 57 years. These fifteen patients totalled 1,886 fits in the year before treatment. At the end of the second year's treatment the total is 494—an average reduction of fully 72 per cent., the lowest individual reduction being 50 per cent. In this group the case of petit mal which I quoted in my last article is again worthy of mention. The year prior to treatment the patient had 404 fits; during the first year of treatment this was reduced to eighteen, and during the past year he has had three fits, the last being in September, 1921. This group, I think, demonstrates the value of persevering with the treatment in chronic epilepsy.

Group II consists of three cases—one of six years' duration, one of ten years' duration, and one of twelve years' duration, at the time treatment by bromide and borax was commenced. In these three cases the fits, a year prior to treatment, totalled 119. The total during the past year was seven. One of the cases, a man of 62 whose epilepsy was of ten years' duration before this treatment commenced, has had no fits since December, 1920, and after a residence of eight years in the institution was discharged as recovered in July, 1921. He has had no recurrence, and is now earning his own living. A second case has gone out on pass—he has had two fits during the past twelve months, the last being in March, 1922.

The changes to be noted in the condition of the patients are: (1) marked general mental improvement; (2) freedom from stupor after fits; (3) disappearance of irritability and quarrelsome tendencies—marked features of epileptics; (4) complete change of habits—patients formerly of degraded habits are now the reverse.

Numerous excellent results among other epileptic patients could be quoted, but I shall confine my notes to a few only. One case, a mental defective and typically epileptic, who formerly had attacks at regular intervals, has had no fits since August, 1921. The following case is nothing short of miraculous.

T. A., aged 17, used to be confined to bed, did not speak, did not appear to understand anything said to him, had many epileptic attacks both by day and night, had to be fed, was of degraded habits—in fact, could do nothing for himself, and was always in a state of stupor. Treatment was commenced in July, 1920, and he had, to begin with, half the adult dose. Very soon his fits were reduced in number and severity. He is now much improved, seldom has a fit, and is out of bed daily. His physical condition is good, he is bright in appearance, answers questions readily, shows a fair amount of intelligence considering his opportunities, assists in the work of the ward, and in appearance and behaviour is the very opposite of the typical epileptic.

Two young patients, aged 17 and 18 respectively, were sent here as epileptic, and have been treated accordingly. So far they have had no fits, and they have now been here one for seven months and the other for twenty months. Another patient, 16 years of age, was admitted last December. Up to

March of this year he had no fits, and was then discharged as recovered.

The following case I saw in private with Dr. McMillan of Shotts, and to him I am indebted for the history.

A. B., a female aged 21, began to have fits when she was 17, and they were becoming more severe and very frequent in spite of treatment with large doses of bromide. In December, 1920, she was put on bromide and borax, and has had no fits since. For the past three months she has taken no medicine, and has had no recurrence. This patient commenced with small doses of borax and bromide, which were gradually increased, and the combination which brought about the good result in her case was borax purificatus 7½ grains, potassium bromide 5 grains, and Fowler's solution 2 minims, three times a day.

The treatment of the eighteen patients mentioned has been as follows. To begin with they were put on potassium bromide 10 grains, borax purificatus 5 grains, and Fowler's solution 2 minims, three times a day. The dose was gradually increased, and I found I obtained the best results with potassium bromide 15 grains, borax purificatus 7½ grains, Fowler's solution 2 minims, three times daily, and this combination gave the results as stated in the above two groups. In addition the patients had a laxative at bedtime. At present I am trying different combinations of the two drugs from the above by way of experiment.

In conclusion, I may say that the continuous treatment has had no deleterious effect on the health of the patients, there have been no gastric or skin disturbances, and, in fact, the general physical condition has improved.

## TRAUMA AND APPENDICITIS.

BY

CHARLES J. G. TAYLOR, M.A., M.D.,

SURGEON, NUNEATON AND DISTRICT GENERAL HOSPITAL.

The following two cases, which have recently been under my care, raise some interesting points in regard to the etiology of appendicitis, and on that account may be worthy of putting on record.

### CASE I.

A. S., aged 18, was playing football on September 30th, 1922, when, towards the end of the second half, he was charged and received a severe blow on the right side of the abdomen from his opponent's elbow, which laid him out for the moment. He vomited, but was able to rise and walk to the dressing room. Whilst changing he vomited again. He then walked about half a mile to a bus, which conveyed him to within a short distance of his home. During the whole time pain in the abdomen was severe. When he arrived home he lay down, and as the pain got no better he, later in the evening, called in his doctor, who thought that he must be suffering from appendicitis, but in view of the history decided to wait till the following morning. The diagnosis then seemed certain. When admitted to hospital at 2 p.m. the temperature was 100°, the pulse 88. The tongue was furled, the abdomen was definitely rigid and tender in the right iliac fossa, the point of maximum tenderness being somewhat below McBurney's point.

At 7 p.m. Dr. E. N. Nason administered an anaesthetic, and the abdomen was opened through a right rectus incision. Omentum presented on opening the peritoneal cavity. A small quantity of slightly turbid fluid was mopped out, and the appendix was then found pointing downwards over the brim of the pelvis, the vessels deeply engorged, and the organ throughout its length covered with patches of lymph. The appendix was removed in the usual manner and the abdomen closed without drainage.

Convalescence was uneventful, except that two days after operation a tense swelling the size of a plum was discovered in the tissues of the right spermatic cord immediately above the testicle. This was diagnosed as a haematoma, and at the time of discharge it had shrunk almost to vanishing point.

On cross-examination after operation this youth informed me that some two months previously he had suffered from an attack of "indigestion" (pain all over the abdomen and vomiting), which lasted for two days and then cleared up. He was positive that when he walked out to the football field he was feeling as well as he had ever done in his life.

### CASE II.

H. V., aged 22, at about 1 a.m. on October 18th, 1922, was working on the night shift down the pit when he had to put forth a violent effort to lift a tub on to the rails. About three minutes later he was seized with sudden acute pain across the lower abdomen and vomited. He was brought out and sent home, when he vomited again three or four times, and the pain continued to be severe. At 9 a.m. he was seen by his doctor, who advised his immediate removal to hospital, but as "his people were not willing" he refused. However, at 6.30 p.m. on the following day he was admitted. The temperature was 99.8° and the pulse 88. He complained of severe pain in right side of the abdomen.

On examination there was tenderness all over the lower abdomen, with increased rigidity; tenderness was very marked over McBurney's point. An anaesthetic was administered by Dr. Bradbury, and at 8.45 p.m. the abdomen was opened by a right rectus incision, and a short, stumpy, acutely inflamed appendix, buried in adhesions, was found behind the caecum. About half a drachm of thin pus free in the peritoneal cavity was sponged out and the operation completed in the usual way, the abdomen being closed without drainage.

He had had a troublesome cough previous to the present illness, and this somewhat complicated his recovery, as he coughed open the skin wound. In other respects convalescence was uninterrupted.

In both of these cases the attack was definitely ushered in by violence—in the one by a direct blow on the abdomen, in the other by a severe strain. An intriguing point in both cases is their bearing on the Workmen's Compensation Act. In the first case, of course, that question did not arise; but supposing it had, I do not think that compensation could have been withheld, even allowing that the patient had had a previous attack, the onset being apparently so definitely the result of the blow. In the second case the influence of trauma is more debatable.

I find on looking through my notes that I have dealt with one other case allied to these. It occurred at Scapa Flow in 1916. A boy, aged 16, from H.M.S. *Conqueror*, was kicked on the right side of the abdomen. He was admitted to hospital ship two days later with tenderness and rigidity in the right iliac fossa, but the temperature was normal. I removed a very long and congested appendix. This case would probably have cleared up without operation.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### THE VARIATIONS OF NORMAL TEMPERATURE.

A PASSAGE in Dr. E. Clark-Jones's article (BRITISH MEDICAL JOURNAL, November 25th, 1922, p. 1026), that ignorance obtains as to what constitutes a normal temperature, leads me to record some investigations I made as a student on my own body temperature in March and April, 1892. I found that thermometers differed by as much as a third of a degree, and selected one which recorded the mean of six as I was unable to procure one with a Kew certificate of accuracy.

I made 170 records of my mouth temperature at intervals of an hour or two during a period of twenty-one days in April, 1892, and, averaging each period, I obtained the accompanying Chart A. I was led to do this because in the previous

CHART A.—Normal day temperature curve while studying, with short periods of slight exercise.

CHART B.—Rise of temperature at five-minute intervals after severe exertion in well-trained condition.

March, during training for the Hospital Rugby Cup final, I had been trying to find out the effect of exercise on the temperature, with some astonishing results. I found that the effect of slight exercise was to raise the body temperature slightly for a short time until perspiration began, when, if the exercise was continued, there was a continuous fall, and a few days before the final cup tie after a two hours' run I found my mouth temperature was 94.6°; Chart B shows the rise afterwards at successive five-minute intervals. At the commencement of vigorous training on March 6th that year after one hour's run I recorded 95.4°, and after half an hour's interval it had risen to 99.1°, and did not return to normal till four hours afterwards. The effect of training was to diminish that rise until it was not perceptible, although the fall was lower.

On March 8th, after one hour's run, I discovered that the urinary temperature was three degrees lower than the mouth temperature at the same time, being 93.7° while the mouth was 95.7°, and when I recorded the mouth temperature of 94.6° the urinary temperature was 99.6.

I find that the urinary temperature is always, even before rising in the morning,  $0.6^{\circ}$  higher than the mouth temperature, and during the day is from one to two degrees higher according to the amount of exercise taken. In the intervals between urination I have taken it at the urinary meatus, and find it half a degree higher than that at the mouth, and the latter is a quarter of a degree higher than that in the armpit even when there is perspiration, and half a degree when the armpit is dry.

Further, the temperature always falls after urination, but there is no perceptible further fall after defaecation unless rectal readings are taken, when they are lower than the mouth reading by  $0.2^{\circ}$  to  $0.4^{\circ}$ . At other times rectal readings are higher than mouth readings up to half a degree when the bladder is full, and consequently I have regarded them as the most unsatisfactory method of getting nearest to the heat of the blood, the changes in the temperature of which we wish to determine.

The fall of the mouth temperature on rising is very striking and absolutely constant and seems to indicate inaction of the heat-regulating centres.

Northwich.

HENRY H. HAWARD, M.B., B.Ch., etc.

### TREATMENT OF MIGRAINE.

A RECENT contribution lauding luminal in migraine prompts record of other experience.

When, despairing of the use of bromides in epilepsy, atropine was added, or when the "mal" was entirely "petit" used alone, hope returned. And very notable successes followed.

In migraine for years the best treatment, unfortunately limited to those cases exhibiting warning symptoms, was found to be hourly administration of calomel to catharsis. Likening migraine to sensory or subcortical epilepsy—that is, to the action of the epileptic poison on the basal ganglia—atropine was tried. From the experience of eight years it may be confidently asserted that the remedy is as nearly a specific as the state of knowledge permits. The dose is 1 to 3 minims of liquor atropinae, thrice a day after meals. Continuous and indefinite administration is unnecessary. A course of three weeks or more to commence with, followed by ten or fourteen days' treatment at intervals determined by the reaction of the particular patient, suffices.

Burton-on-Trent.

H. D. O'SULLIVAN, M.B., B.Ch.

## Reports of Societies.

### ACUTE OEDEMA OF THE CERVIX.

A MEETING of the Edinburgh Obstetrical Society was held on December 13th, 1922, with the President, Dr. J. LAMOND LACKIE, in the chair.

Dr. W. F. T. HAULTAIN read a communication on "Acute oedema of the anterior lip of the cervix." In a case which he had had under observation, the patient, a 5-para, had always been healthy except for eclampsia with her first child. On examination when she was a week overdue, the head was low down in the pelvis, the abdomen somewhat pendulous, and the os uteri the size of half a crown. The cervix was then normal, except that the anterior lip was slightly tongue-shaped. Labour was induced with castor oil, quinine, and pituitrin, and pains started next day; a child 8 lb. in weight was born within four hours without difficulty, the placenta being expelled ten minutes later. Before the placenta was expelled a large mass was found lying beside it which was thought to be another lobe of placenta, but when the placenta was expelled the mass remained. On Dr. Haultain's arrival, three-quarters of an hour after birth of the placenta, he found a tumour the size of a medium-sized Champetier de Ribes's bag, and shaped like it, dilating the vulval orifice. It was purple in colour, and extremely tender on pressure. On vaginal examination it was found to be continuous with the anterior lip of the cervix, and there was no pedicle of attachment. The uterus was well contracted, and there was no unusual bleeding from the vagina, while the patient's general condition was excellent. The tumour became rapidly reduced in size, and in half an hour had entirely disappeared within the vulval orifice. Next morning the only relic was a slight tongue-like thickening of the anterior lip of the cervix, similar to that found before the onset of labour.

The literature on the subject (added Dr. Haultain) is extremely scanty, only some 13 cases having been reported. All have occurred in multiparae between 20 and 40, the previous confinements having been normal. In two cases it occurred with an abortion, two of the women were phthisical, one had a large ovarian cyst, one suffered from very marked constipation, and in two cases it was associated with prolapse. All the others were healthy. The oedema usually began about the seventh month, but in two cases it came on just before labour, and in one at the third month. Labour was spontaneous in nine cases, forceps were required in two, one came off prematurely at the beginning of the ninth month, and one died after an operation for ovarian cyst. The striking features in all the cases were: (1) the sudden onset; (2) the rapid disappearance of the swelling; (3) the tendency which it has to come and go during pregnancy; (4) the absence of difficulty in the birth of the child; (5) the absence of pain. The etiology is obscure. Jolly believes it to be due to an inflammatory oedema caused by infection or by a toxin, and to be of the nature of angio-neurotic oedema. Geyl thinks it is due to stagnation of blood by an acute kink between the cervix and the lower uterine segment, and that the slight increase of abdominal pressure during pregnancy exaggerates the defect.

Dr. JAMES YOUNG showed lantern slides illustrating an early ovum which he considered to be not more than fourteen or fifteen days old. The blastocyst was smooth all round, showing no projections of the mesoderm into the trophoblast. Unlike the Teacher Bryce ovum, the trophoblast consisted almost entirely of cells of the Langhans type.

Dr. W. F. T. HAULTAIN showed a specimen of myosarcoma in the main horn of a two-horned uterus in a nullipara aged 42. The only symptom had been menorrhagia with no loss of weight or disturbance of general health. The tumour mass completely filled the main body and blocked the cervix, the smaller horn being unaffected.

Dr. HAIG FERGUSON showed: (1) A large cervical fibroid enucleated by abdominal section. (2) Ruptured pregnancy in a rudimentary horn of a bicornute uterus. There had been three months' amenorrhoea, followed by an acute attack of abdominal pain, vomiting, and collapse. The abdomen was opened and found to be full of blood, while the four months' foetus and membranes had escaped into the abdominal cavity. There was no apparent connexion between the ruptured half and the other half of the uterus or with the vagina, although a somewhat doubtful communication had been demonstrated microscopically. The corpus luteum of pregnancy was present in the ovary of the opposite side. (3) Fundal carcinoma in a double uterus in which the original septum had been destroyed by the malignant growth; the patient was a sterile married woman aged 65. (4) A large uterine fibroid with twisted pedicle and intraperitoneal haemorrhage. The abdominal cavity was found full of blood, and the fibroid, a large subperitoneal one, was found to be twisted one and a half times from left to right upon its pedicle. Blood was flowing freely from a rent in a vein about the size of a slate pencil, which was one of many coursing over the surface of the fibroid. Supravaginal hysterectomy was followed by complete recovery.

### HEART DISEASE IN PREGNANCY.

A MEETING of the North of England Obstetrical and Gynaecological Society was held at Manchester on December 15th, 1922, with the President, Mr. HAROLD CLIFFORD, in the chair.

Mr. A. LEYLAND ROBINSON (Liverpool), in a paper on heart disease in pregnancy, said that the conclusions formed by Angus Macdonald in 1878 were in the main surprisingly applicable at the present time, although some modifications had to be made in view of the results of recent cardiological research. The latter had shown that cardiac murmurs did not necessarily indicate serious disease and that many systolic bruits were innocent if not actually physiological. The myogenic theory of heart conductivity had been demonstrated and a rational explanation provided for many types of formerly obscure cardiac irregularity. The discovery of auricular fibrillation had brought to light an important mechanism in the production of heart failure. Prognosis was now determined by the efficiency of the heart muscle and its capacity for work. A pregnant woman with heart disease was primarily a heart case, but the

influence of pregnancy on cardiac disease and the special dangers of labour formed a problem of great importance to the obstetrician. Pregnancy affected the heart and circulation in several ways: (1) An increased output of blood was demanded by the growing tissues (uterus, breasts) and by the placental circulation; (2) the uterine tumour produced certain mechanical effects by simple pressure on the base of the lungs and on the heart itself, which was displaced upwards and rotated to the left; as a result the pulmonary circulation was impeded and the right heart embarrassed. Pregnancy, therefore—and in particular labour with its severe muscular effort—implied cardiac strain and called up the reserve power of the heart: in health that reserve was quite adequate, but in disease such physiological response might be impossible, and heart failure would then occur.

Mr. Leyland Robinson then referred to 39 cases from the Liverpool Maternity Hospital, comprising 26 cases of mitral stenosis, 6 of mitral regurgitation, 2 of aortic regurgitation, and 5 of functional cardiac disease. Of these patients 5 died—4 from mitral stenosis, 1 from aortic regurgitation and mitral stenosis. The effect of treatment was shown by the result in 17 cases of mitral stenosis (10 with severe and 7 with advanced disease). Of 12 women who received careful pre-natal supervision, one died (a difficult breech delivery); of 5 women who received no such treatment all died. Accurate cardiological diagnosis was essential before undertaking treatment, as many systolic bruits and arrhythmias had no pathological significance and no treatment was required. In the presence of organic disease rest and prolonged observation were of first importance; the physiological activities of the patient must be limited and made to conform with the capabilities of the heart muscle. The appearance of signs of incipient heart failure (such as the persistence of crepitations at the pulmonary bases) indicated that the cardiac reserve was being seriously encroached upon and demanded special treatment. Drugs of the digitalis group were chiefly called for by auricular fibrillation, whilst haematinics, regulated exercise, and nourishing food were of great value in improving the tone of the cardiac muscle. The termination of pregnancy might be called for under special circumstances: In early pregnancy, for the incipient heart failure of aortic disease (because compensation once broken could not be restored by treatment), or for a progressive decompensation in mitral stenosis when there was no response to digitalis. In advanced pregnancy the induction of premature labour was permissible for mild cases with full compensation, but was definitely contraindicated in the presence of heart failure near term.

The conduct of labour was a great responsibility and required careful consideration. During delivery *per vias naturales* morphine was extremely helpful in reducing the voluntary efforts of the patient, and forceps might be employed to expedite delivery. Caesarean section would give better results, particularly in the case of a primipara, where (1) the disease was severe and the heart barely compensated and the reserve poor, or (2) if there was the least reason to suspect delay or difficulty in delivery. Although many cardiac patients successfully passed their one or more confinements and the immediate result appeared to be satisfactory, the strain on the heart was rarely transient but usually prolonged and sometimes permanent and irremediable. Apart from parturition, many cardiac diseases were naturally progressive, as endocarditis, which was prone to occur, might convert a quiescent lesion into an active and progressive one. It was therefore doubtful whether repeated pregnancies should be allowed, and, if not, the question of sterilization would have to be cautiously considered in those cases where it was not possible to prevent conception.

Mr. Leyland Robinson's paper was discussed by Dr. DOBBIN CRAWFORD (Liverpool), Dr. W. E. FOTHERGILL (Manchester), and Dr. J. E. GEMMELL (Liverpool).

### TREATMENT OF EMPYEMA.

At a meeting of the Oxford Medical Society held at the Radcliffe Infirmary in December, 1922, Dr. F. J. HATHAWAY (Windsor) read a paper on the treatment of empyema. He began by remarking that the treatment of empyema—namely, incision and drainage by a tube—had not changed for the last one hundred years. He hoped that soon the open drainage of a chest with a sucking wound would be looked on as a surgical abomination. This was the subject he had been

working on for the last five years and at last the immediate closure of pneumococcal empyema was being recognized and justified. He pointed out that the post war surgeon was not satisfied with the eradication of disease or of pus alone, but put before himself a higher ideal—namely, restoration of function—provided he ran no risk of septicaemia.

Dr. Hathaway quoted from his experiences of war surgery on the knee-joint, peritoneum, and pleura, and showed that in these regions immediate closure of wounds had been more than justified by restoration of function. In regard to empyema, he pointed out that the structure of the pleura was peculiar in that a rigid thorax contained a collapsible lung; that therefore in the treatment of empyema with a collapsed lung it was essential that the lung should be encouraged to expand as fully and as early as possible, for it was not until the lung fully expanded that pleural suppuration would end. This full and early re-expansion of the lung could only be produced by the method of immediate closure, because this method did away with the two great hindrances to lung expansion—the effects of atmospheric pressure and secondary infection. After quoting his own experiences in gunshot wounds of the chest when surgeon to a casualty clearing station in France, Dr. Hathaway briefly reviewed the history of wounds of the chest, pointing out that even in the thirteenth century Henri de Mondeville immediately closed the chest in order to avoid a "sucking wound." Felix Wurtz in 1563 recommended, with the era of gunshot wounds, that chest wounds should be closed, as also did Guthrie and Baron Larrey in the nineteenth century. During the American civil war, the Franco-Prussian war, the Boer war, and at the beginning of the late war there was no improvement. But in 1915 the era of immediate excision of gunshot wounds, introduced by Sir Henry Gray of Aberdeen, led the way for the immediate closure of wounds of the chest, abdomen, and joints.

As an important point bearing on the treatment of empyema, the crippling effects on the lung itself by adhesions were described in even a simple haemothorax. Mr. James Berry, in a recent paper, had laid down this axiom: "A good surgeon is one who knows when to use a drainage tube and when to remove it." Dr. Hathaway went further: "A good surgeon is one who realizes that restoration of function is more important than the use or abuse of a drainage tube." He then dealt with the method of immediate closure of pneumococcal empyema. Early and complete restoration of lung function could only be accomplished by complete operation—namely, by freeing the visceral pleura of all adhesions—and by doing away with atmospheric pressure and a sucking wound and with secondary infection.

The three most important points in the technique of operation were:

1. Bacteriological examination of pus after aspiration. He did not advocate immediate closure in any but pneumococcal cases. He would not think of doing so in a mixed staphylococcal and pneumococcal case, or pure staphylococcal or pure streptococcal cases. Here he advocated the use of a "passage tube," also called a rubber "dam," with closure of greater part of the wound, or the use of Carrel-Dakin treatment in streptococcal cases.

2. Sufficiently large incision and resection of one or of two ribs in order to allow the whole hand to be introduced into the pleural cavity, to remove all pus and fibrinous clots and especially all adhesions which might have formed on the visceral pleura causing crippling effects on lung expansion.

3. After operation daily aspiration of the fluid put into the chest, with an aspirating syringe between the lips of the wound. This was quite painless. The fluid used for filling up the pleural cavity was either a 2 per cent. suspension of iodoform in paraffin or more frequently flaine. A daily bacteriological examination of the aspirated fluid was made, and under this treatment the organisms gradually diminished until the fluid became sterile, when the aspiration could be stopped.

In conclusion Dr. Hathaway claimed that he had proved his case and that the operation of immediate closure of pneumococcal empyema was established and justified, and that his work of the last five years was being recognized. As pleural suppuration would only end with full lung expansion, then if the technique of early and complete operation was carried out the mutilating operation of Estlander would no longer be necessary. Convalescence would be shortened and the physio-therapeutic results would be much better than they ever were with the use of a drainage tube and a sucking wound. Restoration of lung function was the aim of treatment, and this was more important than mere evacuation of pus.

## PIT-HEAD HYGIENE.

At a meeting of the Society of Medical Officers of Health, held on December 15th, 1922, with the President, Dr. T. EUSTACE HILL, in the chair, a paper was read by Dr. COLSTON WILLIAMS, Medical Officer of Health for the county of Glamorgan, on pit-head baths and other amenities in colliery areas.

He defined pit-head baths as such provision as would enable the miner to go to his work like other men in ordinary clothes; at the pit-head or near by to change and store them safely before putting on his pit clothes. That when he had finished his job of work he could have a warm bath to remove the sweat and coal dust, and so be able to return to his home clean and in clean clothes ready for his meal. After describing in detail the existing unsatisfactory bathing arrangements in the homes of the colliers, transgressing too often the laws of decency, and involving a great deal of hard work on the part of the wife, Dr. Williams referred to the effect of industrial habit on the minds of those engaged in particular trades. The collier in the street or in a public conveyance, returning from his work with blackened face and dirty clothes, was conscious that he compared unfavourably with others not bearing upon them the unpleasant marks of their craft. Such a feeling influenced action in the life of the coalfields, and it was harmful and dangerous that a large body of men should feel they were a class apart because of a social disadvantage. The Coal Mines Act of 1911 enacted that a mine owner must provide accommodation and facilities for bathing and drying the clothes of the colliers if two-thirds of the workmen in a ballot expressed a desire for it and undertook to pay one-half the cost of maintenance, this sum not to exceed threepence a week for each workman liable to contribute. At the end of 1920 there were seven pit-head installations—four in Lancashire, one in Yorkshire, one in Scotland, and one in South Wales. The last was erected at Treharris, in the Aberdare valley, at a cost of £8,000, through the generosity of certain shareholders in the Ocean Colliery Company, and is used by over 60 per cent. of the workmen employed. The apathy of the workmen and (strange though it might seem) of their wives was largely responsible for the lack of bathing facilities elsewhere. The welfare fund created through the Mining Industry Act of 1920 was built up by a levy of a penny on each ton of coal raised, and it was estimated that in the five years of the statutory life of the fund about five million pounds will be produced. The objects of the fund were to improve the social well-being, the facilities for recreation, and the conditions of life of those working in or about mines, and to promote research and mining education.

Dr. HERBERT JONES considered that coal dust in itself was not harmful and should not be looked on as ordinary dirt, and if the colliers could be prevailed upon to see that they must rid themselves of it as the miller must get rid of the flour that clings to him the apathy of the colliers towards pit-head baths might be lessened. He was surprised to find that the soldiers who had returned to the coalfields and who had become accustomed to the admirable bathing facilities in many fixed camps had not insisted on pit-head installations. Failing baths at the pit-head, where they were obviously the most economical, he suggested the erection of ranges of baths near to groups of houses.

Dr. E. H. T. NASH said that colliers were very difficult to get out of grooves, due in great measure to the grey, dull monotony of their lives. Many of them were prejudiced against pit-head baths because of the fear of taking cold after a hot bath. If they could come home clean it would have an immense influence on their state of mind and their self-respect would be very much increased. He could not agree with the suggestion that coal dust was not real dirt or that there would be any advantage in having ranges of baths away from the pit-head. Dr. T. L. THOMSON believed that within the next twenty years pit-head baths would be the rule and not as now the exception, for the children of to-day, who are being educated by school inspection and in other ways to the advantages of cleanliness, will as the men and women of the time demand them. Dr. T. SHADICK HIGGINS considered that the conditions of employment of many workers was a distinct menace to our present social order, but a promising feature of present-day civilization was the more human attitude adopted towards their workpeople by many employers of labour. He could not agree that coal dust was not real dirt.

The PRESIDENT was in favour of pit-head baths rather than communal baths and said that in the county of Durham the latter would be impracticable. The Durham colliers, though many of them lived in two-roomed houses, were the cleanest of their class, and the most industrious. There was a great deal to be said in favour of making pit-head baths a charge on the industry, and this view was held by some colliery owners. He suggested that the welfare fund might be used in the support of child welfare work and similar enterprises. In Durham county the colliers and their wives took very great interest in the voluntary welfare centres.

## JONNESCO'S OPERATION.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, held on December 15th, 1922, with the President, Sir W. DE C. WHEELER, in the chair, Mr. A. K. HENRY described a new method of excising the left cervico-thoracic ganglion of the sympathetic. He said that Jonnesco in 1920 had reported a well authenticated case of angina pectoris associated with aortic atheroma, successfully treated by ganglionectomy of the sympathetic in 1916. The man reported himself to Jonnesco four years later. He had had no recurrence of pain; he was a syphilitic, and admitted that he was still addicted to alcohol and tobacco. Jonnesco reported his second case in 1921, and Tuffier at the same meeting also recorded a success by this method. In the first case the middle cervical and cervico-thoracic ganglia were resected on the left side. In the second, Jonnesco removed in addition the superior cervical ganglion as its removal was easy. Tuffier, however, in his successful case, limited the resection solely to the left cervico-thoracic ganglion. The operation had been suggested to Jonnesco by François Franck with a twofold object: first, to interrupt afferent impulses from the aorta which are responsible for the pain of the seizures; secondly, in removing the cervico-thoracic ganglion, sympathetic filaments ascending on the vertebral artery were interrupted, which might carry dangerous constrictor impulses to the vessels of the brain stem.

Mr. Henry thought, too, in view of the fact that the first patient's pulse rate increased gradually after the operation, that sympathectomy possibly diminished vagal "grip" upon the heart. Removal of the cervico-thoracic ganglion was the essential part of the procedure, and by the accepted antero-lateral route it was difficult. The cervico-dorsal ganglion lay at the back of the thoracic inlet upon the joint between the first costal head and the first dorsal vertebra, in the little space between the anterior scalene muscle and the longus colli. Into this space on the left side were crowded the common carotid artery, the subclavian artery, the vertebral branch of which passed inwards and upwards behind the carotid, and was separated from that trunk by the inferior thyroid artery and thoracic duct. The vertebral vein, passing down to end in the subclavian, lay anterior to the vertebral artery, and received the deep cervical vein. These structures occupied planes anterior to the ganglion, and helped to screen it from the surgeon using the antero-lateral route. The veins especially were easily wounded.

The relation of the first costal head to the ganglion suggested a more direct approach by costo-transversectomy at this level, and with this Mr. Henry had dealt in a previous communication. Further investigation, however, had suggested to him that, as the tip of the second dorsal transverse process was almost level with the head of the first rib, an approach as direct, and less cramped, might be obtained by removal of this process, together with the proximal part of the second rib. It was not difficult to mistake the second rib for the first, and an accurate method of locating the second rib after division of the vertebro scapular muscles and the upper serratus posterior was described. The "strategic interval" occupied by the summit of the pleural dome, between the caudal end of the cervico-thoracic ganglion and the vertebral artery, was demonstrated by means of a model. This interval, which appeared after the intact pleural dome had been depressed, facilitated the safe separation of the cephalic end of the ganglion from the artery. The model also showed the connexions and the peculiar angulation of this compound ganglion. It was essential to divide these connexions in due sequence. The points of the procedure were illustrated by means of lantern slides, and colonic etherization by the safe method of Dr. Alfred Boyd, combined with regional anaesthesia, was suggested as the anaesthetic of choice.

## RICKETS IN INFANTS.

A MEETING of the London Association of the Medical Women's Federation was held on December 12th, 1922, at the Elizabeth Garrett Anderson Hospital, with the President, Dr. LOUISA MARTINDALE, in the chair, when Dr. HELEN MACKAY read a paper entitled, "Rickets in infants: some views on its etiology based on twenty months' work in Vienna."

Dr. Mackay first summarized briefly the results of recent experiments on animals carried out by McCollum, Hess, Mellanby, and others, showing that light and diet were etiological factors in rickets. Diets which produced rickets in rats exposed to insufficient light might become adequate if the exposure to light was increased, and increased exposure to light would cure rickets in rats which had developed the disease in the laboratory on a defective diet. The dietetic factors of primary importance appeared to be the amount in the food of an organic antirachitic factor present in small amount in milk fat and in large amount in fish oils, with the amount and relative proportion of calcium and phosphorus. Other factors, such as excessive carbohydrate, probably played a contributory part. Under the auspices of the Medical Research Council and the Lister Institute of Preventive Medicine, a party of British workers, consisting of Miss Harriette Chick, Dr. Elsie Dalyell, Miss Margaret Hume, Miss Henderson Smith, and the speaker herself, had been studying rickets in infants in Vienna, where exceptional facilities were placed at their disposal. At the University Kinderklinik, where cases of rickets were known to develop, Professor Pirquet set aside beds for the investigation of the disease; sixty cots in all were available. Infants were observed on the diet in routine use at the Kinderklinik, which consisted of full milk with heavy carbohydrate additions, and also on a contrasting diet arranged by the British workers, which consisted of milk with the addition of one to one and a half drachms of cod-liver oil. A five months old baby frequently received about one pint if it was on the first diet, and one and a quarter pints if it was on the second. The results, taking a radiographic standard of diagnosis, were clear cut: in summer no infants on either type of diet developed rickets, whereas in winter babies on the diet of full milk and carbohydrate developed the disease, while those on the second diet did not. All the infants who developed rickets were diagnosed radiographically between January and April, most frequently at about the age of 6 months. Curative observations demonstrated the fact that exposure to sunlight out of doors (in direct sunshine or even in the shade), exposure to the light of the mercury vapour quartz lamp, and the administration of cod-liver oil brought about rapid calcification of the rachitic metaphyses and healing of the bone lesions. All three methods of treatment, however, were not equally effective in improving the general health, the most marked improvement occurring in infants treated out of doors. Other workers had pointed out, said Dr. Mackay, that the seasonal incidence and geographical distribution of rickets were determined chiefly by light.

## Reviews.

## WOMEN DOCTORS.

To write such a book as Dr. LOUISA MARTINDALE'S *The Woman Doctor and her Future*,<sup>1</sup> one of the main purposes of which appears to be to justify the position which women now occupy in medicine, is, in these days, almost a work of supererogation. Women have more than justified their position in medicine and the public has accepted their advent as one of the more natural and desirable developments of feminine "emancipation." It would seem, in fact, that none of the many new professional careers now open to women presents so many attractions to the woman student as medicine, and the available teaching institutions find it difficult to deal with the numbers who seek to gain admittance. Medical women occupy responsible and distinguished posts in our hospitals; they undertake important work at maternity and child welfare centres; and in general practice, more particularly in connexion with diseases of women and children, they occupy an honoured place in the public service. The early struggles of the pioneers of the medical women's movement in the last century are described by Dr. Martindale with the enthusiasm begotten of unstinted admiration. We

are given glimpses of the lives of Dr. Elizabeth Blackwell the first woman to obtain a medical degree, Dr. Sophia Jex-Blake, the founder of the Edinburgh School of Medicine for Women, and Mrs. Garrett Anderson, who instituted the New Hospital for Women, now called the Elizabeth Garrett Anderson Hospital. The opposition with which these first women doctors had to contend has given to their determined and heroic struggles the atmosphere of a sacred crusade, waged against the forces of reaction. This opposition was undoubtedly unjust and appears now in the light of experience to have been altogether mistaken.

Whereas at the beginning of this century the number of medical women in this country was inconsiderable, there are now nearly three thousand women students as against some ten thousand male students in our medical schools. Without in any way reverting to the antagonistic attitude of the past the question may be asked, Does not this proportion meet the public demand at the moment? It is obviously of great importance to the interests of medical women that the supply of women doctors should not suddenly exceed a demand on the part of the public which is steadily but slowly increasing. In this connexion we fear that the prospects which Dr. Martindale offers to the newly qualified doctor in her chapter on "The Position of Women in Medicine" are more roseate than many of the younger medical women have experienced. Undoubtedly many women prosper in private practice, but not many can at once earn incomes of "between £1,000 and £4,000 a year." A newly qualified medical woman often has difficulty in finding an opening in private practice, partly because there are not so many practices for women "on the market" as for men, and partly because the special nature of the work which most women take up makes it difficult for them to find openings suitable to their experience. The fourth chapter, entitled "A Doctor in the Making," gives some excellent advice to women students who have decided to embark on the medical curriculum and details the facilities which exist for their training in this country. The final chapter, on "The Woman Doctor's Future," describes the opportunities for service in hospital work, in research, in public health duties, and in political life.

The book is animated by that high idealism which appears to have inspired all the early pioneers of medical education for women: no woman student could read it without a feeling of pride in the courageous and public spirited work of her predecessors.

## GREEK BIOLOGY AND MEDICINE.

*Greek Biology and Greek Medicine*,<sup>2</sup> by Dr. CHARLES SINGER, is the first of a series entitled "Chapters in the History of Science," under the general editorship of this indefatigable worker. Of the four sections of the present volume three—namely, those on Greek biology before Aristotle, Greek biology after Aristotle, and Greek medicine—are reprinted, with some corrections and additions, from *The Legacy of Greece* (1921), edited by Mr. R. W. Livingstone with the object of conveying some idea of what the world has learnt, and can still learn, from ancient Greece in various realms of the spirit and intellect. Of the voluminous works ascribed to Aristotle the scientific fall into three groups, dealing with physics, with biology, and with psychology and philosophy in their biological bearings. The work on physics commanded respect for two thousand years, but after Galileo's time it ceased to receive attention, whereas the biological observations which had attracted little interest during the Middle Ages came in for close study from the sixteenth century onwards, and especially in the nineteenth century.

Much of what is ascribed to Aristotle is, of course, spurious, and his biological works are, in form at least, so unlike his general style that they probably represent his notes imperfectly edited rather than a considered work. Dr. Singer emphasizes the number of first-hand observations made by Aristotle and refers to the suggestions—none of them very satisfactory—advanced to explain an achievement so difficult to understand. His observations are considered in detail with many quotations, and this admirable essay may with advantage be read together with Professor D'Arcy W. Thompson's enthusiastic and pleasantly written article on the same subject in *The Legacy of Greece*. Dr. Singer prints out that as a physiologist Aristotle is on a lower plane than as a biologist, and is in much the same position as he is as

<sup>1</sup> *The Woman Doctor and her Future*. By Louisa Martindale, M.D., R.S. Lond., J.P. London: Mills and Boon, Ltd. 1922. (Demy 8vo, pp. 198; 8 illustrations. 7s. 6d. net.)

<sup>2</sup> *Greek Biology and Greek Medicine*. By Charles Singer. (Vol. I of *Chapters in the History of Science*. General editor, Charles Singer. Oxford: The Clarendon Press. 1922. (Cr. 8vo, pp. 123; 21 illustrations. 2s. 6d. net.)

a physicist; since he never dissected the human body his ideas about the functions of the vascular and nervous systems were hazy. As a naturalist he was at his best as an original observer, but is weaker and less comprehensible when theorizing on the views or work of others.

In his account of biology before Aristotle Dr. Singer makes the best use possible of the material available, scanty though it be. He discusses the information to be gleaned from early Greek art showing the close observation of animal forms, and finds in the Hippocratic collection the first systematic account of animals. It is indeed not surprising that it is in connexion with medicine that biology was studied by the ancient Greeks, for their science and philosophy were essentially anthropocentric and they took interest in animals in so far as observations of them bore on human problems.

The essay on biology after Aristotle begins with the botanical work of Theophrastus, a pupil of Aristotle, though a pedestrian when Aristotle was a creature of wings. Theophrastus stood in much the same relation to his master as the morphologists of the second half of the nineteenth century did to Darwin. With the death of Theophrastus (287 B.C.) pure biological science practically vanished from the Greek world, and science became an applied study subservient to medicine. This assertion is supported by reference to the Alexandrian school, Dioscorides, Celsus, and others; full attention, however, is given to Galen's work also.

Greek medicine is described in its general characters at its best period; our debt to the Hippocratic school is clearly established. The outstanding merit of Greek medicine is held to be that it is based on observation and not on hypotheses. The character of the Hippocratic collection is fully set forth, and its strength from a clinical point of view is shown to lie in the admirable description of cases. Anatomy, physiology, and pathology were weak before the time of the Alexandrian school, and yet the therapeutic equipment of the Hippocratic physician is said to have been much the same as that of the medical man of seventy years ago. This is perhaps an overstatement, but it need not be denied that the Hippocratic school, though without the help of anatomy, experimental physiology, and pathology, gained, by a process of pure scientific induction, an insight into the practice of medicine that was little surpassed until the nineteenth century had begun.

## TWO POSTHUMOUS WORKS OF BRETONNEAU.

THE publication for the first time, on the occasion of the centenary of his work on diphtheria, of Bretonneau's treatises on enteric fever and specificity, with an introduction and notes by Dr. Louis DUBREUIL-CHAMBARDEL,<sup>3</sup> may be regarded as an important event in the history of medicine. "The work of Bretonneau," says Professor Gilbert in his preface to this volume, "is a trilogy composed of diphtheria, enteric fever and specificity." The treatise on diphtheria, which is known to English readers from the translation in the New Sydenham Society's publications, was published in 1822, but the other two essays, in spite of the entreaties of Bretonneau's two most distinguished pupils, Trousseau and Velpeau, have remained in manuscript until now. Dr. Dubreuil-Chambardel, a distinguished medical historian of Tours and a descendant of Bretonneau, has divided his introduction into three chapters, the first dealing with Bretonneau's teaching at Tours, the second with his three principal works, and the third with the medical doctrines prevalent from 1808 to 1829, dealing especially with the gastro-enteritis of Broussais (1808), the entero-mesenteric diseases of Petit and Serres (1813), and the typhoid fever of Louis (1829). A vivid picture is given of Bretonneau's activities at Tours, and an anecdote is related illustrating his scientific enthusiasm which nearly cost him his life. In his anxiety to confound his opponents, who maintained that the disease prevalent in the town was quite distinct from that which he had described in the hospital patients, he used to make nightly visits, accompanied by his intern, to the cemetery, where very rapidly he opened the graves of the children who had died of croup, made an examination of the fauces and larynx, and beat a hasty retreat under fire from the neighbours, who had mistaken the pair for robbers.

The treatise on enteric fever, or *dothinentérie* (a word

derived from the Greek *δοθήνη*, a pustule, and not from *δοθέρη* as wrongly stated on page 44), consists of four sections: the first is anatomical, and the second clinical; the third deals with the relations of the anatomical lesions to the symptoms, and the fourth with the contagious nature of the disease. Bretonneau was the first to show that the essential lesion of enteric fever was in the small intestine with exclusive affection of the agminated and solitary glands, a fact which accounted for the rarity of the disease in infancy and old age. As regards the clinical picture of typhoid fever Bretonneau is to be credited with the first description of the osseous and articular complications, the affection of the larynx, and the involvement of the eyes and ears. Lastly, Bretonneau was the first to describe the contagious nature of the disease, which had been denied by Andral, Bouillaud, and Chomel, and regarded as doubtful by Louis.

The treatise on specificity as originally planned consisted of four chapters, the first dealing with diphtheria, the second with enteric fever, the third with dysenteric inflammation, and the fourth with malarial infection. The last two chapters, however, were never written, although a paragraph was devoted to dysentery in the treatise on enteric fever, where a description is given of the specific character of dysenteric lesions.

Dr. Dubreuil-Chambardel draws attention to a number of aphorisms in the chapter on enteric fever, from which we may select the following as foreshadowing the doctrines of bacteriology: "Many disorders and notably a large number of inflammations are determined by extrinsic material causes, by actual substances of external origin or at least foreign to the normal condition of the organic structure." The influence of Bretonneau's teaching on specificity is to be found in the celebrated clinical lectures of Trousseau, who acknowledges his "eternal gratitude" to his master in the dedication of his work.

## DISEASES OF CHILDREN.

DR. BERNARD MYERS'S *Diseases of Children*<sup>4</sup> is a short and reliable handbook: it covers the whole field and follows the usual plan of textbooks on this subject. Introductory chapters on the special anatomy and physiology of children, the requisite data on growth, and the dietetics of infancy, are followed by others on the diseases of the newborn, the nutritional disturbances of infancy, and the diseases of the various systems. Two final chapters give a short account of the important infectious diseases, and practical details of treatment applicable to the period of childhood.

The author has been able to command the collaboration of others in certain departments of the subject. Thus Dr. Mackenzie Wallis contributes a very useful chapter on biochemistry in children's diseases; Professor Eyre writes on the employment of serum vaccines; there is a short account of the physiology of digestion by Sir William Bayliss; and there are other short articles on special subjects written by those with special knowledge. These special contributions increase the value of the book without interfering with its unity; and, indeed, the field covered by a textbook on this subject is too wide to be adequately covered by one man. It is no easy task to deal fully and clearly with a large and often complicated subject within the limit of about five hundred pages; that could only be done by presenting a very careful digest of the author's experience and of his study of the literature. Dr. Myers has performed his task well, but would have done even better if he had embodied in his book more of his own personal experience and had given us less of the opinions and dicta of other writers. For example, he is a follower of Finkelstein, and gives a faithful transcription of Finkelstein's classification of the dyspepsias of infants. But he does not furnish the reader with convincing examples from his own clinical material illustrating the Finkelstein doctrines, and his account of the symptoms and signs in the different groups does not provide a clear clinical picture. So that the case for Finkelstein's classification cannot be said to be strengthened by the chapter on this subject. On the whole, and considering the modest size of the book, an accurate account of the commoner diseases is given, modern views and doctrines are kept well to the front, and the details of treatment are fully and clearly described.

<sup>3</sup> *Traité de la dothinentérie et de la spécificité de Pierre-Fidèle Bretonneau*. Publiés par la première fois d'après les manuscrits originaux avec un avant-propos et des notes par le Dr. Louis Dubreuil-Chambardel. Préface de M. le Professeur Gilbert. Paris: Vigot Frères. 1922. (Fr. 12.)

<sup>4</sup> *Practical Handbook on the Diseases of Children*. By Bernard Myers, M.C.G., M.D. (Edin.), M.R.C.P. (Lond.). London: H. K. Lewis and Co., Ltd. 1922. (Demy 8vo, pp. xvi + 548; 61 figures. 21s. net.)

## GUY'S HOSPITAL REPORTS.

THE quarterly number for October, which completes the volume for 1922 of the *Guy's Hospital Reports*,<sup>5</sup> contains ten papers; half dealt with abdominal subjects, and of these three are by the indefatigable editor, Dr. A. F. Hurst. In a paper on chronic appendicitis and appendicular dyspepsia he insists on the great value of  $x$  rays and of Bastedo's inflation test in the diagnosis of this condition; operation should not, he considers, be undertaken until the diagnosis has been thus confirmed; it is not clear to what extent adhesions binding down the appendix may be concerned in the production of pain after inflation of the colon; but as Bastedo's sign may be positive in the absence of adhesions it is probable that the chief factor in this test is distension of the diseased appendix. Dr. Hurst also describes chronic obstruction of the duodenum by the mesenteric vessels (chronic duodenal ileus), and in conjunction with Dr. J. A. Ryle two examples of "epigastric hernia," which are really fat prolapses from the fat of the falciform ligament of the liver and not true hernias. In an investigation into the state of the gastric secretion in appendicitis and cholelithiasis Mr. T. G. Bonar found that of 40 cases of chronic appendicitis with symptoms confined to the right iliac fossa 22 showed achlorhydria or hypochlorhydria, which probably favours appendix infection; whereas among 25 cases of appendix dyspepsia none had achlorhydria or hypochlorhydria, and 22, or 88 per cent., showed hyperacidity. Mr. W. H. Bowen describes with commentaries 5 cases of perforation of the large bowel presenting some features of interest.

In the fourth instalment of his stimulating studies on tumour formation Dr. G. W. Nicholson discusses acquired tissue malformations, and after giving many examples from his own experience concludes that certain anomalies that arise in the tissues long after their development is completed are in every way comparable with congenital malformations. Mr. Malleon's notes on dental histology are freely and successfully illustrated by forty-one figures. Professor Pembrey, Dr. Hunt, and their collaborators now bring out the second part of their elaborate investigation into tests for physical efficiency, and find that the pulse ratio—namely, the ratio between the pulse rate for two minutes immediately following the given *mild* muscular exercise and the pulse at rest—is a good indicator of physical fitness. The results of six months' routine use of the urea concentration test are summarized by Dr. Hugh Barber, who has found it of practical value in confidently excluding renal disease—more especially in the condition in middle life which he terms "leaky kidney," and remarks that the excellent health of two such men with albuminuria of ten or more years' duration is due to the absence of treatment. In a brief note Dr. J. Ryle records two cases of traumatic thrombosis of the brachial artery due to prolonged pressure of a crutch. This interesting fasciculus also contains the index for the completed volume.

## ORTHOPAEDIC NURSING.

EVERYONE who has had the advantage of seeing the work done at the Shropshire Orthopaedic Hospital at Baschurch or at Oswestry will welcome the notes on *Orthopaedic Nursing*<sup>6</sup> by the Honorary Superintendent, Miss A. G. Hunt, R.R.C. We say advisedly "everyone," for, although these notes are intended for orthopaedic nurses and probationers, they contain many hints which will be found useful by surgeons. This hospital has been remarkable for the thorough way in which open-air treatment has been carried out in it for upwards of twenty years and for the enthusiasm, skill, and administrative ability of the author of this pamphlet, to which so much of its success is due.

The outstanding symptoms of tuberculosis in the various regions of the body are clearly set forth and the method of using splints and plaster-of-Paris for each of them is described in detail. The illustrations and instructions are clear and definite and some of the hints given are enforced with that humour which is characteristic of the author. It may be objected that the diagnosis of tuberculous lesions is no part of a nurse's business, but in carrying out the admirable

scheme of after-treatment in the villages of Shropshire nurses may have the first opportunity of detecting disease and of providing the "stitch in time" by handing cases on to the surgeon, and to do this they must have the necessary knowledge. We hope that Part I of these notes may soon be followed by Part II.

## NOTES ON BOOKS.

THE fact that a second edition has been called for within two years of the appearance of the first is sufficient testimony to the value of Dr. MODI's *Textbook of Medical Jurisprudence*.<sup>7</sup> The author has followed the arrangement usually adopted in textbooks on this subject, and much of his material is identical with that relating to this country. Dr. Modi has, however, included such extracts from Indian law as are appropriate to his subject, particularly sections of the Indian Evidence Act, Criminal Procedure Code, Indian Penal Code, Lunacy Act, and Poisons Act. He also gives full and interesting accounts of various vegetable poisons unknown in this country. It would seem that most of these are taken for the purpose of procuring abortion. We note with interest that powdered glass is frequently administered in India with homicidal intent, usually mixed with food such as rice or flour. If well powdered it does not as a rule have any ill effects. This book is written primarily for students, and it can be recommended to them as sufficient for their purposes. It will also be useful to medical and legal practitioners.

Among the numerous students' gazettes the *St. Bartholomew's Hospital Journal* has for many years past held a high place both for the general standard of its contents and for the excellence of its humour. In 1909 a selection was made from the large number of light verses and sketches that had appeared from time to time, and these were issued in book form under the title *Round the Fountain*, the profits from the sale being devoted to the Nurses' Home Rebuilding Fund. The first and second editions were soon exhausted, and now a third and enlarged edition has been published.<sup>8</sup> This comic anthology will be relished by all old Bart.'s men, recalling memories of happy moments of gossip round the fountain in the square. Some of the reprinted pieces are mainly of local interest, but many others will be appreciated by medical men whose student days were passed elsewhere. Of the new numbers the six little poems entitled "Disrespectful Ditties" seem to us particularly neat, and a burlesque set of questions for out-patients, modelled on the army field postcard, is quite one of the best things of its kind we have seen.

Mr. KEITH MONSARRAT's new volume, *Poems, 1920-1921*,<sup>9</sup> shows increased command of his medium and a greater power of getting his thought through the barrier that separates mind from mind. Many of the pieces are in blank verse, and three at least—"Sigurd," "In Rome," and "Samson"—in dramatic form. In these he philosophizes, showing himself a lover of man, but in them also peeps out the lover of nature whose greatest solace is in the beauty of this world, "sweet with the scent of gardens after rain." Herein is his strength, and many will think the poem, "To a Garden," the best in the book. There is also an experiment in galloping rhythm sufficiently successful to be repeated.

Dr. WILLIAM BARR, whose volume of poems, *Passing Songs*,<sup>10</sup> has just been published, is without doubt an easy versifier, with an excellent sense of rhythm and a conservative taste in rhyme. His emotions, however, are never very deep, and he is inclined to echo other poets, great and small. When one remembers those other noble lines, beloved of every anthologist, the following—

"My feet are blistered with the stone  
That paves the way for many dead,  
And yet—my spirit is my own  
And nobly do I hold my head"

—rather taste like so much Henley and soda-water. Many of Dr. Barr's poems convey the suggestion that they would go well to music, of the lighter school—Hermann Löhr rather than Schumann or Schubert (although the latter, one observes, is now also to be numbered among the musical comedy composers)—and that is an excellent criterion of light verse, particularly in these days of *vers libristes*.

<sup>5</sup> *Guy's Hospital Reports*, No. 4, October, 1922, vol. Ixiii (vol. ii, Fourth Series). Edited by A. F. Hurst, M.D. London: Henry Frowde, and Hodder and Stoughton. (Med. 8vo, pp. 122; 67 figures. Single copies numbers 22s.)

## THE MUSTERING OF THE PROFESSION.

### MEDICAL SERVICE IN THE GREAT WAR, 1914-19.

THE story of the manner in which the medical profession in Great Britain responded to the call of the country in 1914 and the following years is well worth the telling. We all remember how first the medical officers of the Reserve and the Territorial Force were called up, and simultaneously we witnessed the crowding of medical volunteers willing to make any sacrifice to serve their fellow countrymen who in such large numbers were joining the service battalions; then came the strenuous effort that had to be made to keep pace with the growth of the Armies—the five armies in France, the army based on Salonika, and the army in Mesopotamia, the Expeditionary Force to the Dardanelles, and the forces engaged in the many lesser operations in South Africa and elsewhere. The Navy and eventually the Air Force also made their own calls, but on a lesser scale. The problem of how to meet the demand for military service while keeping going the life of the country at home was presented to all callings, but to none in so direct a way or on so large a scale as to the medical profession. The home demand was perhaps more imperative for it than any other. Both calls were met successfully mainly because the Government consented to allow the profession to deal with its own difficulties in its own way through machinery it itself established.

Dr. J. R. CURRIE, who, until his recent appointment to be Professor of Preventive Medicine at Queen's University, Kingston, Ontario, was medical officer to the Scottish Board of Health, has, at the request of the Scottish Medical Service Emergency Committee, of which he was a member, prepared a record of the work done in Scotland. It is published in a volume entitled *The Mustering of Medical Service in Scotland 1914-1919*,<sup>1</sup> and has a preface by Sir Alfred Keogh, who makes a graceful reference to the value and magnitude of the work done by Dr. Norman Walker, the convener of the committee. The opportune publication of this volume affords an occasion for recalling in chronological order the chief points of the medical policy which was developed to provide medical officers for the armies, while at the same time safeguarding the interests of the people at home, both in Scotland and in England and Wales.

#### THE FIRST FIVE MONTHS—1914.

At the outbreak of war in August, 1914, when men were dimly conscious of the magnitude of the task which was before them, it was natural that many people should ask themselves in what manner they could best contribute to the success of the issue. In the beginning these questionings were more frequent with individuals and with small bodies than with larger associations, whose multifarious duties invited them to carry on their "business as usual." Thus it was that the earliest stirrings in the medical profession were found in individual volunteering for service in the R.A.M.C., and amongst Divisions and Branches of the British Medical Association, rather than in the Central Council of the Association.

#### *The First Move in Scotland.*

The earliest recorded administrative effort is that of the Scottish Committee of the Association, of which the late Dr. J. R. Hamilton of Hawick, that fine type of broad-minded practitioner, was chairman. Dr. Hamilton was quick to see that the departure of the Reserve and Territorial medical officers made it imperative that action should be taken for carrying on their civilian duties alike in their own interest and in that of the public. Acting at once, he caused a conference to be held in Edinburgh so early as August 12th, 1914, to which were invited representatives of the medical faculties of the Universities and Royal Colleges in Scotland, to consider what steps should be taken to meet the emergency that had arisen owing to so many medical practitioners having been called up for active service. By August 22nd a committee was in being as a "bureau or clearing house for information, for the purpose

of assisting to meet the immediate difficulties in regard to medical practice among the civil population." This body, created for only the one limited purpose, became the Scottish Medical Service Emergency Committee, whose history is now told in Dr. Currie's volume. The Committee as originally constituted was composed of fifteen medical men, seven of whom acted *ex officio*, while eight were elected by the conference.

The seven *ex-officio* members were the Presidents of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow, and the deans of the Faculty of Medicine of the Universities of St. Andrews, Glasgow, Aberdeen, and Edinburgh.

Of the eight elected members, six, who were in general practice, included five office-bearers of the British Medical Association—Dr. John Adams (Glasgow), Dr. G. C. Anderson (Fife), Dr. John Gordon (Aberdeen), Dr. J. R. Hamilton (Hawick), and Dr. John Stevens (Edinburgh). Dr. John Playfair, president of the Medical Guild, completed the six. Of the two remaining elected members, one was the deputy chairman of the Scottish Insurance Commission, Dr. John C. McVail, and the other the Direct Representative for Scotland on the General Medical Council, Dr. Norman Walker.

To them the Committee at its first meeting added Dr. J. R. Currie, medical officer of the Scottish Insurance Commission. Mr. T. H. Graham, librarian of the College of Physicians, was appointed secretary.

About the same time—August, 1914—a local medical committee was formed in Dundee, and schemes for emergency medical services were drafted there, at Southampton, at Exeter, by the London Panel Committee, and in various other districts.

It is worth noting as a matter of history that all these local movements in England as well as Scotland were concerned primarily with the maintenance of an adequate medical service for the civilian population and with the preservation of the practices of the men called up for service with the forces. Within a few months, however, the main concern of the medical profession became the provision of medical officers for the army; while later still the drain upon the profession for service abroad once more brought civilian needs to the forefront, and the difficult task of holding a balance between the demands of the army and the needs of the civilian population had to be faced.

While these local efforts were in progress the Central Office of the British Medical Association had opened a list for retired medical practitioners willing to offer service, and had indicated to the War Office its readiness to make any appeal that might be desired.

In the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of September 5th, 1914, a suggestion was made for establishing a reserve of medical officers for the army through the machinery of the Association. The proposal was submitted to the branch of the War Office known as A.M.D. I, and it was suggested to that department that the army of 1,000,000 men then contemplated would require more medical officers than were available; that civilian practitioners would be more quickly absorbed into the Service if they had some preliminary training in army methods; and that the British Medical Association offered excellent machinery for establishing in this way a reserve of medical officers with some preliminary training. If this proposal had been acted upon the foundations of a Central Medical War Committee would have been laid in September, 1914. But A.M.D. I turned down the offer; the authorities of the Association did not feel able to act without the approval of the War Office, and the formation of a professional committee for England and Wales was thereby delayed for nine months.

#### THE SECOND YEAR—1915.

#### *The Provisional Committee of the British Medical Association.*

Beyond the development of local activities for the protection of practices, and sundry proposals for the gratuitous treatment of the dependants of men on service, nothing further seems to have happened until January, 1915. At the Council meeting of the Association on January 27th of that year, it was proposed by the late Sir James Galloway "that in order to increase the efficiency of service and to economize the resources of the medical profession, matters arising from the withdrawal of medical men from civil practice to serve with the military forces of the Crown be referred for consideration to a committee of the Association, with instructions to take such action as may appear desirable." These powers were given to a committee consisting of the Chairmen of the Standing Committees, with power to co-opt other members. This

<sup>1</sup> *The Mustering of Medical Service in Scotland 1914-1919*. Being a record of the work of the Scottish Medical Service Emergency Committee in the war. By J. R. Currie. With preface by Lieut.-General Sir Alfred Keogh, G.C.B., G.C.V.O., C.H., late Director General of Army Medical Services. Copies (price 3s. paper, 4s. 6d. cloth) may be obtained post free on application to T. H. Graham, Librarian, Royal College of Physicians, Edinburgh.

committee discussed the grievances of individual medical officers, which were already beginning to be numerous, and made a collection of the evidence thus provided; but it did not feel itself competent to deal with broad questions pending the consideration of the position by the Representative Body. At the same time the then Director-General at the War Office, Sir Alfred Keogh, no doubt hoped that the committee would be useful for the purpose of providing more officers for the service. The disasters at Gallipoli in February and March were not foreseen by the Cabinet, but, coupled with other events which occurred at about the same time, they helped to impress on everyone the bigness of the job the British Nation and the Dominions had undertaken. The Director-General found it necessary to approach the committee with a request for assistance in obtaining at once 2,000 more medical officers. The request rendered visible the irony of the refusal of A.M.D. I in September, 1914, to join the British Medical Association in establishing a reserve of officers for emergencies.

#### *The War Emergency Committee of the Metropolitan Counties Branch.*

At this stage certain members of the Metropolitan Counties Branch made representations to the Council of that Branch and early in April, 1915, a War Emergency Committee of the Branch Council was appointed "for the purpose of organizing the profession in the area of the Metropolitan Counties Branch so as to meet the necessities of civil and military practice." Of this committee Dr. James Galloway was appointed chairman, Dr. Charles Buttar deputy chairman, and Dr. R. Crosse and Mr. Bishop Harman secretaries. At its first meeting, on April 19th, the committee was informed that certain tentative action had already been taken, that Colonel Peterkin, of the London Command, had been interviewed in order to ascertain the military requirements in the matter of medical officers, and that the central authorities of the Association had been approached with regard to the provision of funds for the committee's work.

One of the results of the formation of this Committee of the Metropolitan Counties Branch Council was that the Council of the Association at its meeting on April 28th resolved, on the motion of Dr. Galloway, to set aside £1,000 "for use in recruiting officers to the Army Medical Service and generally to aid the War Office in providing an efficient medical service." It will be seen, therefore, that from January to April, 1915, attempts at co-operation between the British Medical Association and the War Office were desultory in nature and unsatisfactory in results. The Army Medical Department was ready enough to obtain medical officers by any method, through the British Medical Association or otherwise; and the British Medical Association was largely concerned in the grievances of individual medical officers. It had, however, been suggested to the Divisions and Branches that they should hold meetings in their areas which the D.D.M.S. of the Command should be invited to attend. In some cases the D.D.M.Ss. wrote sympathetically, in others they sent representatives. Though this measure of co-operation may have been of value locally in some cases, it had no noticeable effect on the broad question of the relation of the Army Medical Department to the civilian profession.

On May 3rd the Committee of the Metropolitan Counties Branch addressed a memorandum to the Committee of Chairmen of Committees; and on May 7th Dr. James Galloway was co-opted to the latter committee; on May 13th Dr. Buttar was invited to attend a meeting of the Committee of Chairmen of Committees, as a representative of the War Emergency Committee of the Branch, and explained that it desired a grant from the £1,000 which had been voted by the Council of the Association, to defray the expenses of carrying on recruiting propaganda. A grant was made, and the War Emergency Committee of the Metropolitan Counties Branch obtained also the loan of a room at the Association's house and the services of two of the Association clerks. A business man was appointed to take charge of the office, and the first piece of work undertaken was to form a register of all practitioners within the area of the Metropolitan Counties Branch, with a record of their age, kind of practice, experience, the war work on which they were engaged, and so on. At the same time there arose the idea of enrolment for military service when required, to which the curious term "voluntary conscription" was later applied. The interest taken by the Director-General and Assistant Directors A.M.S. in the interim report by the Metropolitan Counties Branch War Emergency Committee

on the information it had obtained was shown by a letter on the subject addressed to the Central Office of the British Medical Association on June 11th, 1915. The Committee of Chairmen of Committees accepted the view that a complete register was necessary, and a War Register of the Association was started.

#### *The War Emergency Committee of the Association.*

The War Emergency Committee of the Metropolitan Counties Branch soon found that it was hopeless to carry on recruiting propaganda for one small patch of the country only, and at the Representative Meeting in London on July 23rd, 1915, they carried a proposal for the extension of the scheme of the Metropolitan Counties Branch to the whole country. The Association was now definitely committed to taking a hand in the organization of the medical profession for war-time service, military and civilian, and the Committee of the Metropolitan Counties Branch ceased its activities. The War Emergency Committee appointed by the Association was constituted as follows:

*Ex officio:* Sir Alexander Ogston, Mr. E. B. Turner, Dr. J. A. Macdonald, Dr. Edwin Rayner.

*By Representative Body:* Sir Clifford Allbutt, Sir William Osler, Sir Arthur Shipley, Sir Jenner Verrall.

*Representatives of the Council:* Dr. R. A. Bolam, Sir James Barr, Sir James Galloway, Mr. Bishop Harman.

*Representatives of the Representative Meeting:* Mr. A. Lucas, Mr. W. J. Greer, Mr. Russell Coombe, Dr. C. Buttar.

*Added subsequently:* Sir Frederick Taylor, Sir Rickman Godlee, Professor Harvey Littlejohn.

Dr. Alfred Cox and Mr. Bishop Harman were appointed secretaries, and gave very valuable services to the Committee until it was dissolved in 1919. The reference to the Committee was wide; and the wisdom of the promoters in making it wide was proved on many occasions subsequently. The Committee was formed—

"To organize the medical profession in such a way as will enable the Government to use every medical practitioner fit to serve the country in such a manner as to turn his qualifications to the best possible use; to deal with all matters affecting the medical profession in connexion with the war; and to report to the Council."

#### *The Scottish Medical Service Emergency Committee.*

The Scottish Medical Service Emergency Committee drew its information from three main sources—the Scottish Corporations and Universities, the British Medical Association, and the Government departments. Though not constituted by any formal election, it was able to make a broad appeal to the profession and to command its confidence. All the members were medical men, so that medical destinies were in medical hands. The convener was Dr. Norman Walker, the Direct Representative for Scotland on the General Medical Council. His wisdom and self-sacrificing assiduity had a large share in the success achieved. Down to the end of 1914 the work was entirely in the civil sphere, arranging with practitioners desirous to get or to give help, drafting agreements as to terms in order to avoid future difficulties, and advising as to reduction of institutional resident staffs. Its first contact with the War Office appears to have occurred late in 1914, when, in consultation with the Scottish Insurance Commission and the Highlands Medical Board, it approached the Director-General, who agreed, as far as practicable, to forbear from removing single practice men when their units received marching orders.

#### *Early Meetings of the War Emergency Committee, England and Wales.*

The War Emergency Committee of the Association met for the first time on July 30th, 1915. Sir Jenner Verrall was appointed chairman. The Committee began the consideration of the War Register and of the protection of the practices of medical men called up for service. The question of organization of local war emergency committees was also discussed, and the Committee also decided to appoint an Executive Subcommittee. On August 4th a letter was received from Sir Alfred Keogh welcoming the formation of the Committee. On August 18th the Executive Subcommittee met for the first time, and Dr. Buttar was appointed chairman. On August 25th "voluntary conscription" was discussed by the full Committee, and on August 30th the Executive Subcommittee began the organization of local war emergency committees, issuing at the same time leaflets on enrolment and on the preservation of practices. At this time the Director-General was asking for 2,500 more medical officers.

*Local War Emergency Committees.*

During September, 1915, the formation of local war emergency committees was in progress, the enrolment system was developed, the question of the age limit for commissions was discussed, and pressure began to be put upon Government departments and public bodies with regard to setting free medical officers of military age. The position already achieved by the Committee was shown by its reception of a deputation from the hospitals in Manchester, and by the fact that certain Government departments made a statement to the Committee as to the medical officers they employed.

*The Growing Demands of the War Office.*

Another interesting development during this month was the receipt of evidence that temporary medical officers in the army were declining to renew their annual contracts. Though the War Emergency Committee was aware already of the frequency of complaint by medical officers that their time was insufficiently occupied, the refusal to renew annual contracts was the first overt expression of the feeling that had arisen. To a certain extent it marked the beginning of the third period of activity in the medical profession—the period of adjustment of army demands and civilian needs. At the meeting of the Executive Subcommittee on October 11th evidence was produced that R.A.M.C. medical officers were in fact not being used to full advantage, and a memorandum on the subject was drawn up for submission to Sir Alfred Keogh. As a result the Director-General modified his demands as regards numbers, and the full Committee decided to continue enrolment, and to endeavour to fulfil what was then beginning to be called the "quota."

*Central Medical War Committee.*

At this meeting, on October 15th, 1915, the title of the Committee for England and Wales was changed from War Emergency Committee to Central Medical War Committee. A suggestion was also made for the formation of a compensation fund for those who might be hard hit in consequence of being called up for service. This suggestion was ultimately developed by the War Emergency Fund of the Royal Medical Benevolent Fund. It was during the month of October, 1915, also that the inauguration of Lord Derby's recruiting scheme began to raise questions of the relation of his scheme to the War Committee's enrolment. The matter was promptly dealt with by the Executive Subcommittee, and on November 8th it was announced that Lord Derby had agreed to recognize the Central Medical War Committee.

*The Entry of the English Insurance Commission.*

In November, 1915, occurred an event of far-reaching importance to the Central Medical War Committee, an event which might have led to deplorable results but for the fact that it introduced into the work of the Committee one of the most brilliant of civil servants. Amongst the Government departments approached at the end of September was the Insurance Commission. This body was naturally concerned with the maintenance of the panel system in face of the continual drain on the civilian profession in response to the demands of the War Office. There is reason to believe that the Insurance Commission for England and Wales considered carefully whether it should set out to establish its own machinery for controlling the supply of medical officers to the army, or whether it should support the voluntary committee which had arisen in connexion with the British Medical Association. The Commission decided to adopt the second alternative, feeling possibly that through an independent body more could be effected in controlling War Office demands than through the Government inter-departmental committee which was already in existence. During the month of October there is evidence that the Insurance Commission was concerning itself with the work of the office of the Central Medical War Committee by means of inquiries and suggestions, and on November 16th it was reported to the full Committee that the Insurance Commission, while declining to nominate representatives on the Central Medical War Committee, suggested co-operation. The Commission had objected to the Committee's method of assessment and was beginning to elaborate its own scheme, but on November 19th co-operation in working out the assessment figures for each area was agreed to by the Executive Subcommittee of the Central Medical War Committee. It was at the meeting of the full Committee on November 24th, 1915, that the momentous step was taken which changed the position of the Committee. Prior to this

meeting there had been informal pourparlers between the heads of the Insurance Commission and the British Medical Association, and the result was that Sir Robert Morant, Chairman of the English Insurance Commission, asked to be allowed to attend the meeting of the Central Medical War Committee and to put certain questions to the Committee. The meeting took place on November 24th. Before the interview it was agreed that the Committee would listen to Sir Robert's questions, and consider its answers when the representatives of the Insurance Commission had withdrawn. But Sir Robert Morant, by means of his dialectic skill, speedily began to obtain answers to his questions. Thereupon it was proposed that the Insurance Commission representatives should withdraw while the Committee reconsidered its position in private. In rejecting this proposal the Committee took the step which led to the intimate association throughout the war of the Insurance Commission with the work of the Central Medical War Committee. There is little doubt that without association with the Insurance Commission, and the assistance it gave in dealing with Government departments, the task of the Central Medical War Committee would have been almost insuperable. At the same time it is very doubtful whether the association between the two bodies would have been successful if there had not been a man of the outstanding character and capacity of Sir Robert Morant at the head of the Commission. Through him it became possible to guide the policy of the Committee on lines which avoided difficulties with Government departments. Through the clerical help obtained from the Commission it was possible to introduce sound business methods into the office of the Central Medical War Committee. And as more and more of the able officials possessed by the Commission became drawn into the work, a combination of official methods with the independent thought of those untrammelled with the bureaucratic routine led to the happiest results. Had the Insurance Commission alone attempted to organize the profession it would have incurred suspicion from all sides. Had the Central Medical War Committee acted alone it would have had to encounter the opposition of Government departments. The combination of the two led to a success which greatly enhanced the prestige of the British Medical Association.

*Third-Year Medical Students.*

In November, 1915, questions arose about medical students in their third year. By this time it was realized, even by the most optimistic, that the war was going to be long, and the question arose whether it might not be wise policy to keep third-year students in the Schools until they qualified, when they could be recruited to make up for the inevitable wastage constantly going on from the Royal Army Medical Corps. Dr. T. W. Shore, of St. Bartholomew's Hospital, was co-opted to the Committee to represent the Deans of Medical Schools; ultimately he became chairman of a very important subcommittee of the Central Medical War Committee. The rest of November was occupied by discussions with the Insurance Commission as to statistics and as to the danger of depletion in certain counties; and with the Manchester Committee on local approval before the granting of commissions. Other matters discussed were the classification of the different kinds of medical practitioners and the question of employment of men of military age in V.A.D. hospitals.

*Completion of Organization for England and Wales.*

By the end of 1915 the Central Medical War Committee had established its position; its scheme of enrolment had been generally accepted, and its classification of medical practitioners had cleared away various objections. Only five areas remained without local medical war committees; attestations of medical men under the Derby scheme were on the way to annulment; and the system by which all applications in England and Wales for commissions were referred to the Central Medical War Committee, which then took the advice of the Insurance Commission, was settled. At the end of December representatives of the Insurance Commission were definitely co-opted to sit with the Executive Subcommittee.

*Completion of Organization for Scotland.*

Meanwhile in Scotland, when applications for commissions became frequent, an agreement with the War Office had been reached under which all names from Scotland were sent by the War Office to the Insurance Commission, who conferred

with the Committee, which intimated to the War Office whether it was satisfied that local arrangements could be made. Then the Scottish Committee became recognized as a recruiting agency, and the Scottish Insurance Commission withdrew, no doubt satisfied with the fact that its deputy chairman and senior medical officer were members of the Committee. In April, 1915, the Special Committee of the British Medical Association had urged the Divisions to comply with the Director-General's appeal to free men for the army by arranging with local military authorities for part-time work being done with troops by civil practitioners. The appeal met with a prompt response. The Aberdeen Branch, indeed, under the presidency of the late Dr. John Gordon, who was also a member of the Emergency Committee, had already established a bureau of medical service at the Royal Infirmary. At the end of 1915, of 3,822 civilian practitioners in Scotland, 1,290 were on service.

#### THE THIRD YEAR—1916.

At the beginning of 1916 the difficulties with the War Office over attestation under the Derby scheme of enrolled medical men were finally adjusted, mainly through the efforts of Sir Robert Morant. This adjustment had been made urgently necessary by the passing of the first Military Service Act. In March, 1916, it was announced that the Army Council had agreed that no enrolled doctor would be taken for general service but would remain in the Reserve until selected for a commission in the R.A.M.C., and that in the case of the unenrolled all cases coming before the Central Tribunal would be decided by that tribunal only after receiving advice from the appropriate representative committee of the medical profession.

#### *The Committee of Reference.*

About this time the Central Medical War Committee came to the conclusion that it could not deal effectively with the staffs of hospitals in London. A request was made, therefore, to the Royal Colleges of Physicians and of Surgeons to appoint an advisory committee to consider the minimum necessity of the several metropolitan hospitals and medical schools, and to advise the Central Medical War Committee on any case in which the question arose of indispensability or of excessive personal hardship. As a result of these representations the Committee of Reference was formed; Mr. F. G. Hallett became its secretary, and the triad of professional committees was completed.

In April, 1916, the system of regular conferences between the Director-General A.M.S. and the Central Medical War Committee was instituted, and was continued until late in 1917. At these conferences many important questions were dealt with, and difficulties between the War Office and the civilian committees were frequently smoothed away.

#### *The Central Professional Committees as Tribunals.*

When the Military Service Bill (Session 2), 1916, was introduced in May the position of the professional committees again came up for consideration. The appointment of these committees as the sole tribunals for medical men was opposed in the House of Commons, but owing to the efforts of Sir Robert Morant a clause providing for the establishment of professional committees was inserted in the House of Lords and became Section 7 of the Military Service Act, 1916 (Session 2). Under this Act regulations drafted by Sir Robert Morant at the end of May were approved, and the Central Medical War Committee and the Committee of Reference became recognized as the Central Professional Committees for England and Wales, and the Scottish Emergency Committee as the Central Professional Committee for Scotland. The Central Medical War Committee was made more fully representative by the addition of Dr. Langley Browne, Dr. Adam Fulton, and Dr. Naughton Morgan. Finally, a suggestion made by the Director-General A.M.S. that the Central Professional Committee should be transferred to the office of the General Medical Council was negatived. The offices of the British Medical Association became a busy hive of clerks sent by the Insurance Commission. The Central Medical War Committee met for the first time as the Central Professional Committee at the offices of the British Medical Association on July 7th. Sir Jenner Verrall and Mr. E. B. Turner became chairmen of the two sections of the tribunal, and ultimately Dr. T. W. Shore was made chairman of a third section.

#### *Proposals for Civilian Training of Disabled Men.*

In August, during the lull which followed the strenuous work of establishing the professional committees as the tribunals for medical men under the Military Service Acts, and while these committees were settling down to their work, questions were raised as to the future of disabled soldiers who would not be fit for further military service. The matter was debated by a joint committee which had been established by the Central Medical War Committee and the Committee of Reference, and the Secretary of State for War was asked to receive a deputation in order that the views of the joint committee might be laid before him. The committee was strongly of opinion that disabled men should not be returned to civil life until an effort had been made to fit them for some occupation in accordance with the capacity that remained to them. Ultimately Mr. Lloyd George, then Secretary of State for War, received three deputations together—a deputation from the Statutory Pensions Committee, led by Sir Cyril Jackson; a deputation from the Unionist War Committee, led by Major Astor; and a deputation from the Central Medical War Committee, led by Sir Clifford Allbutt and Sir Jenner Verrall. While expressing sympathy with the policy urged by these deputations, Mr. Lloyd George plainly could not, or would not, adopt that policy. He stated that the matter was being reported on by Sir Walter Lawrence; and in the end very little result followed this piece of work by the joint committee of the Central Medical War Committee and the Committee of Reference.

#### *Proposed General Mobilization for Civilian Work.*

During August of this year a suggestion for the mobilization of unfit men of military age for civil work was made to the Central Medical War Committee by the War Office. This seems to have been the origin of the many suggestions for mobilization of the whole medical profession which continued to crop up from time to time, but did not materialize even when made in the later stages of the war by the Ministry of National Service. In November, 1916, the possibility of the raising of the compulsory age for military service was mentioned by Mr. Russell Coombe, who suggested that it might be necessary to ask for powers to mobilize all medical men up to the age of 55. The history of the movement within the profession for its complete organization, under medical control, for civil and military work, independently of any age limit, is told—with special reference, of course, to Scotland—by Dr. Currie with careful impartiality. It had the hearty and almost unanimous support of the medical organizations which dealt with the question, but the whole project was cut across by the creation of the new Department of National Service under Mr. Neville Chamberlain as Director-General. In December the Central Medical War Committee agreed to support the proposal for mobilization of the whole profession, and appointed a deputation to meet Mr. Neville Chamberlain, in company with deputations from the Committee of Reference and the Scottish Emergency Committee.

During the year 1916 Colonel John Atkins was appointed to sit with the Central Medical War Committee to represent the Director-General A.M.S., and also to represent Sir John French in respect of matters connected with Home Defence. Dr. Wheaton sat with the Committee as representative of the Local Government Board; and in April Colonel Thom undertook duties as representative of the Army Medical Department which had been fulfilled by Dr. Galloway before he was sent to France.

#### THE FOURTH YEAR—1917.

The difficulty of maintaining efficient attendance on the civilian population in the face of the continued and increasing demands of the army led to a series of investigations, of propositions, and of negotiations with the War Office, which ended only when the arrangements for the supply of medical men for the army were transferred to the Director-General of National Service. In February, 1917, the question of mobilization of the whole profession raised in December, 1916, was again under discussion; it was proposed also that warning should be issued to enrolled men between 41 and 45 that they might be called up, and a local arrangements subcommittee was appointed to advise the Executive Subcommittee.

On March 14th and 15th a conference was summoned by the Director-General of National Service, under the chairmanship of Sir Donald MacAlister, to answer certain questions with regard to mobilization of the whole medical profession.

In view of the possibility of such mobilization Dr. Mary Bell was appointed a member of the Central Medical War Committee to represent women practitioners; and Mr. Hallett submitted a memorandum on the financial aspects of national service for doctors.

Opinions and recommendations of the Conference were submitted in a unanimous report to Mr. Neville Chamberlain, who desired time to consider it, and requested that the proceedings be not made public at the time. His consideration appears to have been prolonged, as the embargo was never removed during his career in the department, and it is only now, with his permission, that the report is formally disclosed by Dr. Currie.

#### *The Derby Calling up Notice.*

In consequence of the pressing nature of civil needs the Central Medical War Committee decided to ask the War Office if men could be released from military service during the winter months. On April 11th the Executive Subcommittee was authorized to report to the Director-General A.M.S. that no further substantial reduction of doctors in civil practice could be made without arousing considerable public dissatisfaction, and that the Committee proposed, therefore, to place the position before the Government. The reply of the War Office was the sudden calling up by the Secretary of State for War, Lord Derby, within seven days of all medical men of military age—that is, under 41. This precipitate action was met by the immediate summoning of a joint meeting of the Central Medical War Committee and the Committee of Reference, and the passing of a resolution, proposed by Sir Watson Cheyne, stating that unless the War Office would undertake not to grant a commission to a doctor whom the committees considered indispensable for civil work the committees could take no further part in the selection of doctors for military service. At the same time a memorandum was prepared for the War Cabinet, setting forth the dangers which would arise from the indiscriminate calling up of all medical men under 41. The result was that the Secretary of State at once withdrew from an untenable position, and requested the committees to "continue doing the excellent work for the War Office that they had done in the past." At the same time Lord Derby asked for 850 doctors at the rate of 100 a week. The Central Medical War Committee replied that it would do its best to fulfil this demand, but could not guarantee to do so in consequence of the disorganization caused by the action of the War Office; at the same time the Committee suggested that attention should be given to the possibilities of economy in the use of doctors in the Army Medical Department, and of the increase of co-operation between the military authorities and the committees, both central and local.

On April 26th a Local Arrangements Subcommittee was formed to take over the consideration of the capacity of each area to supply medical officers for the army. Dr. T. W. Shore was appointed chairman of the new subcommittee, which proceeded to make an analysis of all the areas in England and Wales. In view of the increasing work of the Central Medical War Committee as the Central Professional Committee, six more members were added.

In consequence of the delay caused by its action in calling up all men under 41, the War Office turned its attention to the possibility of obtaining the help of American doctors, and to the calling up of Territorial officers *à la suite*. Both procedures led to difficulties which had to be dealt with by the Central Committees. In July the Review of Exceptions Act led to further difficulties, which were smoothed over by Dr. Galloway, but the impossibility of providing the 850 medical officers asked for by Lord Derby caused the Committee to address the Prime Minister on the desirability of an inquiry into the future requirements of the army. At the end of July the Director-General A.M.S. was informed of the approaching end of the civil supply of medical officers, and a letter to the same effect was sent also to the Secretary of State for War.

#### *Medical Recruiting Boards.*

Between the months of May and July the Central Medical War Committee dealt with many other matters, such as the staffing of provincial hospitals (in conjunction with the British Hospitals Association); the possibilities of establishing central surgeries in certain areas; the use of dentists in the army (raised by the British Dental Association); and the preparation of a register of all medical officers in the services, with a view to the steps it would be necessary to take in

the event of demobilization. A special joint conference was also arranged on the question of reconstituting the medical recruiting boards. This conference was held in August, and eventually a scheme was drawn up which formed the basis of the reconstitution effected by the Director of Recruiting (Sir Auckland Geddes) and Dr. Galloway. A Recruiting Medical Advisory Board, upon which representatives of the Professional Committee sat, was appointed in October, and the advice of the local Medical War Committees was used in the appointment of recruiting medical boards.

#### *A Committee of Inquiry in France.*

At the beginning of August, 1917, a rumour reached the Central Medical War Committee that the War Office had decided to send to France a committee of inquiry into the use of medical officers in the army, and a request was sent to the War Office that the inquiry should be extended to the army in Great Britain. This committee of inquiry consisted of Sir Frederick Taylor, Sir Rickman Godlee, Sir Watson Cheyne, Sir Harold Stiles, Dr. Norman Walker, Dr. Charles Buttar, and Dr. J. B. Christopherson. Sir Francis Howard was appointed to take charge of the committee as chairman, and Dr. Christopherson became the secretary. The committee spent the whole of September in France, but was not permitted to extend its investigations to this country, although this would have been within its terms of reference. It sent its report to the War Office in December, but nothing further was heard of it, although the War Office professed to have adopted many of the recommendations.

#### *Attempts to Estimate Future Army Demands.*

In November, 1917, Dr. Galloway (who had become Chief Commissioner for Medical Services, Ministry of National Service) brought before the Central Medical War Committee the possibility of the raising of the military service age. At the end of the month arrangements for the supply of medical men to the army were transferred to the Director-General National Service, and direct communication between the Central Medical War Committee and the Director-General A.M.S. practically ceased. In December discussions began with the Ministry of National Service regarding the supply of doctors for the army; it became clear that the annual contract for medical officers would have to go; and the Minister (then Sir Auckland Geddes) was asked for the estimated net demand of the army for the ensuing year, whether the Ministry was satisfied that medical officers in the R.A.M.C. were being utilized to the best advantage, and whether the Ministry had considered any kind of relief that could be given to the profession in the bill for the amendment of the Military Service Acts shortly to be introduced.

The characteristic feature of 1917 was the growing feeling that over-recruitment of the profession was being demanded by the War Office. The difficulty of discovering the truth was not diminished by the refusal of the War Office to publish the report of the Howard Committee which had been sent to France. From Dr. Currie's book it does not appear that this difficulty was felt in Scotland as acutely as it was in England. Probably the position of the Central Medical War Committee in London, with its greater facilities for obtaining information, made it more acutely alive than the Scottish Medical Service Emergency Committee to the dangers of unsupervised demands by the Army Medical Department. Thus it arose that with the reconstitution of the Ministry of National Service under Sir Auckland Geddes in November, 1917, the Professional Committees, as has been said, ceased to have direct relations with the War Office and became associated with the Medical Department of the Ministry of National Service.

#### *THE FIFTH YEAR—1918.*

The first duty of the Ministry of National Service in 1918 was to attempt to ascertain the position of the R.A.M.C. as regards wastage and to budget for the supply of medical officers for the ensuing year. At first it was announced that no further increase in establishment was asked for at the moment, and that wastage would be made good largely by means of the newly qualified, by a system of replacement of demobilized medical officers, and by expediting the work of tribunals. At the end of January, however, there were hints of further demands by the Army Medical Department. The Central Medical War Committee promptly called attention to

the impossibility of providing further large numbers of officers; to the suspicion that still existed as to the lack of economy in the use of officers in the R.A.M.C.; and to the delay in publishing the report of the committee which went to France. The Insurance Commission also protested against the presentation of a fresh demand so shortly after it had been stated that no need existed. The Central Medical War Committee estimated that under existing powers only 100 more medical practitioners could be made available for commissions during the ensuing year; it presented a memorandum on the impossibility of meeting demands; it proposed various methods for relieving the situation; and in March the Committee replied to a further demand by suggesting that the War Cabinet ought at once to take the matter into consideration.

At the end of March the German offensive in Picardy entailing severe losses on the R.A.M.C. led to another medical emergency, to meet which the Central Medical War Committee put forward a scheme for obtaining volunteers upon a guarantee that they would only be used for the immediate emergency, and would return to civil life in three months, or at most six months, from the beginning of their service. The authorities would not accept this condition, although they agreed that each case should be reviewed on application at the end of the crisis or in six months' time at the latest; and that the officers would then, if possible, be released. The refusal of the guarantee probably spoilt the scheme; at all events only 27 volunteers were obtained.

The Military Service Act of February 6th, 1918, gave power to the Minister of National Service to cancel certificates of exemption from military service granted on occupational grounds. To cope with the additional work placed on the Ministry the Professional Committees were asked to assist the Ministry in arranging for additional National Service medical boards, as well as for medical boards for discharged soldiers. Thus at a time when the War Office was pressing the civilian profession for more medical officers additional work was being thrown upon medical men in providing medical officers for National Service Boards.

#### *Age Limit Raised: Proposed Mobilization for Civilian Medical Service.*

The Military Service (No. 2) Bill, 1918, introduced two provisions that applied to doctors as apart from the rest of the community. In the first place the limit of age for military service was fixed at 55 as against 50 for the rest of the population; and secondly, a provision was made that a certificate for exemption on occupational grounds was to be subject to the condition that the practitioner should undertake such professional service, and under such conditions, as the Director-General of National Service might, after consultation with the medical tribunal and in concert with any Government department concerned, deem best in the national interests. In other words, the principle of vocational control by a Government department was introduced. These provisions were the nearest approach to mobilization of the whole profession that was ever attained. The second provision was the result of prolonged debate between the Ministry of National Service and the Central Medical War Committee which had arisen from the inquiries of Sir James Galloway from the Local Arrangements Subcommittee with regard to co-operation and substitution on February 5th, 1918. On April 5th the Ministry of National Service asked the Professional Committees (1) whether the raising of the military service age would induce other practitioners to move to depleted areas, (2) whether the time was opportune for methods of reorganization and co-operation in order to release younger men. The Central Medical War Committee replied that an organized attempt should first be made to obtain substitutes voluntarily. The Scottish Medical Service Emergency Committee was inclined to the view that substitutional medical practice was unavoidable and favoured a plan of agreed action, subject to any compulsory powers to be furnished by the bill.

With the passing of the Military Service (No. 2) Act, 1918, the connexion between the Professional Committees and the Ministry of National Service became closer, and a Government official, Mr. Vivian, was attached to the office of the Central Medical War Committee to assist the secretary and to be a liaison officer with the Ministry. But the committees still retained considerable powers of criticism, and were able to obtain modifications of the proposals of the Ministry in several directions. The Central Medical War Com-

mittee proceeded with the task of working out a system of substitution, and also dealt with the regulations for the special tribunals dealing with doctors. The Committee approved the appointment by the Ministry of National Service of officials who were to visit the local medical war committees for the purpose of inquiring on the spot into local conditions. A special subcommittee was formed to consider the financial aspects of substitution arrangements. An estimate of available Grade 1 medical men between 43 and 46 was made. In July the Central Medical War Committee was constituted a medical tribunal, and the local medical war committees were recognized as local committees under the Military Service Regulations, 1918. In September the Treasury agreed to the financial proposals with regard to substitution, and the Central Medical War Committee suggested a conference with the authorities controlling the military hospitals in the country before substitution was finally adopted. In the meantime a medical examination of all remaining medical men up to the age of 55 had been made.

In January, 1918, the Central Medical War Committee received a request from the Committee of Reference for a joint meeting with regard to the certificates of medical practitioners in the matter of food rationing. From this meeting arose a small committee which was appointed to advise the Food Controller, Lord Rhondda. Later on conferences were held with the Medical Women's Federation with a view to obtaining its help in economizing man power, and information about women practitioners was added to the card register. In June the Committee of Reference assisted in formulating the lines upon which information should be asked as to the staffing of provincial hospitals. The general principles for the conduct of central surgeries were investigated.

#### *The Last Demand.*

From time to time during the year the Army Medical Department continued to make fresh demands, but it was beyond the power of the committees to satisfy these demands to the full under existing powers. The last demand came on October 1st, and was represented to be an urgent need. In reply, the Local Arrangements Subcommittee made several suggestions, such as expediting the examination of students, the volunteering of young doctors for a period of three months, an appeal for voluntary substitutes for men accepting the three months' service, and the ultimate adoption of compulsory substitution. Within three weeks, and before any of these suggestions had been given a trial, the possibility of an early peace arose. At the same moment the first bad epidemic of influenza that had occurred in this country during the war broke out, and the policy of the Professional Committees in endeavouring to maintain a fair standard of efficiency in medical attendance on the civilian community in the face of the urgent demands of the Army Medical Department was justified. Though the task of the profession in this country in coping with the epidemic was hard, and though the sufferings of those unable to obtain medical attendance were great, the difficulties would have been infinitely greater but for the persistent efforts of the Professional Committees during 1917 and 1918 to force the War Office to justify its requirements.

#### DEMobilIZATION—1918-19.

Questions relating to demobilization at the end of the war had been raised as early as August, 1916, and again by Mr. Russell Coombe in March, 1917. In August, 1917, a subcommittee was appointed by the Central Medical War Committee to deal with this matter, and met for the first time under the chairmanship of Dr. Adam Fulton on September 19th. In November, 1918, conferences arranged by the Interdepartmental Committee of Medical Services, set up by the Ministry of National Service, were attended by representatives of the Professional Committees, and schemes for demobilization were drawn up. These schemes were never carried out completely owing to the action of the Secretary of State for War, Mr. Winston Churchill, which was announced at a meeting of the Interdepartmental Committee on February 24th, 1919. Shortly afterwards the Ministry of National Service ceased to exist, and the duties of the Professional Committees came to an end, though the Scottish Committee continued in direct relation with the naval and military authorities until the end of the year.

## NEW YEAR HONOURS.

## KNIGHTHOODS.

MEMBERS of the British Medical Association throughout the world will be only second to his medical friends in the North of England and his old pupils in congratulating Dr. David Drummond on receiving the honour of knighthood in the list issued on New Year's Day. Sir David Drummond, who for many years was physician and is now consulting physician to the Royal Victoria Infirmary, Newcastle-on-Tyne, won his spurs as a pathologist, a subject he taught in the Newcastle School of Medicine for many years. He is now Professor of the Principles and Practice of Medicine in the University of Durham and Pro-Vice-Chancellor of that University; he is also President of the University of Durham College of Medicine, and is one of the most popular members of its teaching staff. He had long been a member and consistent worker for the British Medical Association, and had for some years represented the North of England Branch on the Council before he was, by the suffrage of his fellow members in that Branch, unanimously nominated to be President of the British Medical Association at the Annual Meeting held in Newcastle in 1921. The success of that meeting, which was most conspicuous, owed not a little to the qualities of mind and heart which had raised Professor Drummond to the position he held. The recognition now afforded to him by the Crown will give immense pleasure to his old pupils and fellow townsmen. We would wish Sir David Drummond the continuance of many years of happy life to enjoy it.

Sir William Hamer, who also receives the honour of knighthood, has worthily filled for many years the high office of Chief Medical Officer to the London County Council, the most important municipal body in the British Empire. He succeeded to that post on the retirement of Sir Shirley Murphy, the Council's first medical officer, to whom Sir William Hamer had been principal assistant. Apart from his official position he is a distinguished epidemiologist and is a doughty defender of the separate existence of the science of epidemiology against encroachment alike by the bacteriologist and the mathematical statistician. He is the author of numerous valuable works on subjects connected with infectious diseases. In 1906 he delivered the Milroy lectures before the Royal College of Physicians, his text being "Variability and persistency of type." The lectures were afterwards published as a book. His staff at the London County Council cannot but be gratified by the honour which the King has conferred upon their chief.

That Sir Norman Walker's name appears in the list under India is doubtless due to his mission not long ago to that country to inquire on behalf of the General Medical Council into the arrangements for the teaching of midwifery in the Indian medical schools. But he has many other claims which well merited earlier recognition. He was chairman of the executive committee of the Highlands and Islands Medical Service Board and, during the war, of the Scottish Medical Service Emergency Committee; he is treasurer of the Royal College of Physicians of Edinburgh, and has been direct representative for Scotland on the General Medical Council since 1907. For several years past he has performed the onerous duties of chairman of the Council's business committee. He is an Edinburgh graduate, physician for diseases of the skin at the Edinburgh Royal Infirmary, and lecturer on that subject in the university.

Sir Bernard Spilsbury's knighthood recognizes valuable service to the Home Office in the medical investigation of crime, and distinction as a teacher in three large metropolitan medical schools. He is now lecturer in morbid anatomy and histology at St. Bartholomew's Hospital Medical College, and lecturer in forensic medicine and toxicology at the London School of Medicine for Women; for many years he was pathologist and lecturer in pathology at St. Mary's Hospital. On relinquishing the pathological work done by him on behalf of London coroners he was lately appointed honorary pathologist to the Home Office in order that his services might still be available for criminal cases of special difficulty. He is examiner in forensic medicine at the University of Oxford, of which he is a graduate, and at the Universities of Manchester and Birmingham. His published works include many important papers on medico-legal subjects, the outcome of long experience in the criminal courts, where his fairness

and his powers of lucid exposition have earned him the respect of bench and bar.

The honour of knighthood is also conferred on two distinguished members of the medical profession in the Dominions: Dr. George Cuscaden, honorary consulting surgeon to the Women's Hospital, Melbourne, late Director-General of the Australian Army Medical Services; and Dr. Hilarion Marcus Fernando, consulting physician to the General Hospital, Colombo, and an unofficial member of the Legislative Council of the Island of Ceylon. He graduated M.D. in 1889, and is a Fellow of University College, London.

The K.C.B. (Military) is conferred on Major-General Sir William Rice Edwards, K.C.I.E., who has just vacated the appointment of Director-General of the Indian Medical Service, and the K.C.S.I. on Sir R. Havelock Charles, G.C.V.O., medical adviser to the Secretary of State for India. He is the first occupant of that office, the establishment of which was an important reform in the organization of the India Office. By his courage and loyalty he has rendered great services to his brother officers and to the people of India. The K.C.I.E. is conferred on Major-General Godfray Giffard, C.S.I., Surgeon-General to the Government of Madras. Sir Milsom Rees, C.V.O., laryngologist to the King and Queen, is promoted to be K.C.V.O.

## COMPANIONSHIPS.

The C.B. (Military) is conferred on Surgeon Rear-Admiral Jonathan Shand, and Lieut.-Colonel and Brevet-Colonel Howard Ensor, C.M.G., D.S.O., R.A.M.C., and the C.B. (Civil) on Dr. F. J. H. Coutts, Senior Medical Officer, Ministry of Health.

The distinction of C.I.E. is received by Lieut.-Colonel Andrew Thomas Gage, I.M.S., Superintendent of the Royal Botanical Gardens, Calcutta, and Director Botanical Survey of India, Bengal; Lieut.-Colonel John Philip Cameron, I.M.S., Inspector-General of Prisons, Madras; Lieut.-Colonel Henry Ross, O.B.E., I.M.S.; and Lieut.-Colonel Alfred Hooton, I.M.S., Agency Surgeon, Kathiawar, Bombay.

Dr. Clare Aveling Wiggins, P.M.O. of the Uganda Protectorate, receives the C.M.G.

Lieut.-Colonel W. J. P. Adye-Curran, O.B.E., R.A.M.C., is promoted to C.B.E. (Military); and the distinction of O.B.E. (Military) is conferred upon Major W. Brooke Purdon, D.S.O.; M.C., R.A.M.C., and Major Henry Thompson Stack, R.A.M.C.

The honour of C.B.E. (Civil Division) has been conferred upon Dr. Henry Curwen, late principal medical officer, Zanzibar Protectorate; Dr. William McNiven Muat, senior medical officer, Wei-hai-wei; Dr. Pryce Peacock (Dublin); and Dr. Henry Percy Pickerill, the last being in recognition of valuable services rendered since the war in connexion with facial and jaw operations on wounded soldiers in New Zealand. Dr. Herbert Torrance, medical missionary, Scottish Hospital, Tiberias, and Major Michael Courtney, I.S.O., I.M.D., Superintendent Central Gaol, Montgomery, Punjab, receive the O.B.E. (Civil Division), the former for valuable services rendered to the people of Palestine.

## KAISAR-I-HIND MEDAL.

The Kaiser-i-Hind medal has been conferred upon Dr. Robert Harper, medical missionary of the American Baptist Mission, Burma; Dr. Nasarwanji Nowroji Parakh, a member of the local Legislative Council, Burma; and Mrs. Isabel Kerr, M.B., medical officer in charge of the Leper Home at Dichpalli, Hyderabad, Deccan.

## PROMOTIONS.

Surgeon Commanders Robert J. MacKeown, O.B.E., Frank H. Nimmo, M.V.O., Richard F. Clark, and Reginald St. G. S. Bond, of the Royal Navy, have been promoted to the rank of Surgeon Captain.

Surgeon Lieutenant Commander Robert Wilbond, R.N.V.R. is promoted to be Surgeon Commander, and Honorary Surgeon Lieutenant Commander Francis J. Hannan, R.N.V.R., to be Honorary Surgeon Commander.

The promotions in the Medical Branch of the Royal Air Force include Wing Commanders Henry Cooper, D.S.O. and Martin William Flack, C.B.E., to be Group Captains; Squadron Leader Harold E. Whittingham to be Wing Commander; and Flight Lieutenants Joseph M. A. Costello, M.C. John H. Wood, M.C., and Arthur J. Brown, D.S.O., to be Squadron Leaders.

SATURDAY, JANUARY 6TH, 1923.

## THE ORGANIZING OF THE PROFESSION FOR WAR.

THE manner in which the medical profession in Scotland and in England and Wales organized itself so that neither the armies nor the civil population should suffer more than the extraordinary calls made upon the profession during the great war rendered inevitable is sketched in an article published in this issue (p. 24). The occasion of the article is the publication of Dr. Currie's book on *The Mustering of Medical Service in Scotland, 1914-1919*, but we have taken the opportunity to dwell at some length on the services of other professional committees which have not hitherto found an historian, as has been the good fortune of the Scottish Committee. A perusal of Dr. Currie's interesting and valuable narrative, and a contemplation of the more summary record we have compiled of the work accomplished in England and Wales by the Central Medical War Committee and the Committee of Reference, suggest certain reflections and may justify an attempt to draw out some of the lessons they contain.

The Scottish Medical Service Emergency Committee owed its origin to the action promptly taken by the late Dr. J. R. Hamilton of Hawick, then Chairman of the Scottish Committee of the British Medical Association. More far-sighted than most of us at the time, he realized the strain to which the medical profession was to be subjected, and from the first grasped the principle that if the strain was to be met it must be through the concerted action of all sections of the profession—the Colleges, the medical teaching faculties, and the general body of practitioners throughout Scotland. He did not hesitate to take action, and gathered a meeting representing all these interests, at which a provisional committee was formed. That committee's sanction to make arrangements for medical vacancies was derived from the goodwill of the profession. A second medical conference in Scotland was also, in a sense, summoned arbitrarily, but the scheme evolved was put into operation by the Scottish Committee of the British Medical Association and then handed over to the Scottish Medical Service Emergency Committee. Later on it was more or less a matter of chance that this Emergency Committee came into charge of medical recruiting, although before undertaking the work it ascertained that it would have the cordial support of the War Office. Throughout all the work of the Scottish Committee the wisdom and assiduity of the convener, Dr. Norman Walker, were of outstanding value, not only in Scotland, but at the War Office.

Medical recruiting under the 1915 scheme was on voluntary lines both *de jure* and *de facto*; and even when compulsory service was introduced for medical men of military age the work continued to be on voluntary lines, since all the practitioners called up for service under the Acts and submitting appeals under them had already voluntarily expressed their desire to serve and their willingness to accept the Committee's decision as to whether they should go into the army or stay at home. When conscription was introduced for the general population it had little practical application to the profession. No Scottish doctor was in fact a conscript; each one who joined did so voluntarily.

Under the Medical Practitioners' Regulations of 1918 a doctor who sought exemption from medical service on occupational grounds got it on condition that he agreed to perform such civil medical service as the Director of National Service might deem best. This provision was much criticized as a form of vocational compulsion. Strictly, however, it was not so, since no doctor who was willing to serve in the army could be made to do civilian work. But for practical purposes it came very near to compulsion.

Owing to the fact that the number of practitioners in Scotland was relatively small, the task of the Scottish Committee was simpler than that which faced the professional committees that sat in London. The difficulties in maintaining adequate medical attendance on large masses of population were great, and their nature and the way in which they were surmounted must be fully considered and understood when the details of any scheme for future emergencies are being worked out. The problem set to the committees was the adjustment of medical activities to new and unexpected conditions. For this purpose it was necessary that a watchful eye should be kept upon every development in connexion with the war, and that a continual stream of new ideas should be kept up to meet or anticipate each development. The committees were fortunate, first, in the men who conceived the ideas; secondly, in the receptivity of their members; thirdly, in the aid they received from certain Government officials; and, fourthly, in the able staff of Government clerks with which the Central Medical War Committee was supplied. Finally, the profession was fortunate in possessing in the British Medical Association a voluntary body which covered the whole country, and through its Divisions was able to maintain direct connexion with members in all parts of the kingdoms. As is mentioned above and is more fully explained in the article published elsewhere, it was the action promptly taken by the Chairman of the Association's Scottish Committee which led directly to the establishment of the Scottish Medical Service Emergency Committee. At the earliest stage of the movement in England the Association provided money and a local habitation for the Committee which eventually became the Central Medical War Committee. It continued its aid throughout the whole existence of that Committee; moreover, it lent to the Committee the services of the Medical Secretary, Dr. Cox, who acted as Secretary to the Committee along with Mr. Bishop Harman, who had been closely associated with the action taken early by the Metropolitan Counties Branch, and had acted as one of the secretaries of the special committee appointed by that Branch.

Though during the war the profession was able to establish an organization which succeeded in supplying the army with medical officers and in maintaining reasonable standards of civil practice, it cannot be assumed that on another occasion fortune will be equally propitious. In England the profession was very happy to have as Chairman of the Insurance Commission a public servant of the eminence and width of view possessed by Sir Robert Morant, an official to second him of the ability of Mr. Vivian, now Registrar-General, and a member of its own body so wise as Dr. James Galloway, who was later on brought within the official fold as Chief Commissioner for Medical Services in the Ministry of National Service. Everyone hopes that "the war to end war" may have achieved its object, but if another war breaks out it may be even less foreseeable than the last. A scheme of medical organization to meet the emergency of a war should be devised and approved during peace. Therefore it will be well that the lessons to be learnt from the development of the Committees in England and Scotland should now be

taken to heart and the scheme for future emergencies built up on the history of the three professional committees. A study of that history may prevent the mistake being made, of which there is already a hint, that in another emergency the organization of the profession shall be in the hands of the Ministry of Health. It was the voluntary basis of the committees which was the root cause of their success; and the early recognition of the value of this principle redounds to the credit of Sir Robert Morant.

### INSULIN IN DIABETES.

THE report by Drs. Banting, Campbell, and Fletcher on the results of the treatment of cases of diabetes mellitus, including some of diabetic coma, in the Department of Medicine of the University of Toronto and the Toronto General Hospital, which is published at page 8, will be read with great interest by the numerous medical workers who, having read the general account of the physiological and therapeutic effects of insulin given by Professor J. J. R. Macleod in our columns of November 4th, 1922 (p. 833), have been looking eagerly for evidence as to the limits within which insulin treatment is likely to be practically successful.

Owing to the difficulty in preparing insulin in large quantities and to the desire to avoid disappointing patients by a cessation of treatment after it has once been begun, the treatment has been applied to some fifty individuals only, and preference was given to those in whom the disease had already assumed the gravest form. It is particularly interesting to note that several children were among those treated. These young diabetics, in whom, according to all previous experience, the prognosis is most unfavourable, responded to insulin as well as older patients. This is a critical test of any treatment for diabetes. Where the condition of the patient permitted he was subjected to a careful preliminary examination, kept at rest in bed, and then permitted to take light exercise for a period. At the same time dietetic measures were adopted to ascertain whether the urine could be rendered by such means sugar-free. Those who became sugar-free were advised to continue dietetic treatment in view of the shortage of insulin. Thus the insulin treatment has been confined to those who resisted carefully planned dietetic treatment.

The record now submitted confirms the earlier conclusion that all the features of abnormal metabolism which constitute diabetes mellitus can be removed temporarily by an adequate dose of "insulin," and can be kept in abeyance by repeated dosage and a suitably adjusted diet. There is a hint at the possibility of a more permanent curative effect, in the reference to the recovery, by certain patients, of "such a degree of tolerance as no longer to require extract to maintain them on a basal diet." No details, however, are given of any such cases, and it would clearly be premature to assume, as yet, that insulin is likely to have a more permanent effect on tolerance than that which has been achieved hitherto by periods of complete abstinence. The question as to how long the advanced case of diabetes can tolerate several daily injections has yet to be answered. There is no reason for assuming that the difficulties will never be circumvented, but their existence must be recognized. It would seem that insulin in some cases not merely renders the urine of sufferers from certain forms of diabetes free from sugar, or reduces the blood sugar within normal limits, but can also enable them to make such improved use of food as to restore them to something approaching normal nutrition and greatly increased vigour.

The claims made in respect of the treatment of cases of complete coma are remarkable. Of ten cases treated,

six, the authors state, are living. "One has recovered and is now aglycosuric without insulin on a diet about double the basal requirement. The other five patients have remained free of symptoms and the urine free of sugar and ketones under dietetic treatment and the daily administration of insulin." Ketones disappear from the urine, but this effect is produced later and ceases earlier than in the case of sugar; simultaneously the normal alkali reserve of the blood is re-established and the signs and subjective symptoms are no longer observed. Statements of this kind are naturally received with caution, and even with some misgiving. The reader is bound to ask whether the authors have possibly been misled by their own enthusiasm. But the facts remain that these six patients are alive, that the improvement which was apparent clinically was confirmed by the laboratory data, and that the observations have been made under the supervision of so skilled and careful a clinical worker as Dr. Duncan Graham, professor of medicine at Toronto. It is satisfactory to be told that the toxic reactions which followed the injections of the extract first used by the Toronto investigators can now be prevented. The description of the symptoms which attend the sudden hypoglycaemia produced by insulin is interesting, especially the account of the nervous phenomena with loss of emotional control. These symptoms read like an account of cases of shell shock that during the war were often seen after prolonged battle strain without exposure to actual explosive effects.

The conditions in which the benefit to be derived from insulin is least open to doubt are the emergencies of diabetes—coma, threatened or already developed, and gangrene necessitating operation. Even if it should prove in the long run that the lifelong maintenance of an increased tolerance, by daily administration, is impracticable, the existence of a remedy which promises to carry the patient past a threatened danger to life, to make possible and safe a necessary but otherwise desperate operation, and which can be brought into play whenever an intercurrent infection lowers the tolerance of the patient for carbohydrates, is bound to be a factor of great importance in the treatment of diabetes mellitus. It is to be hoped that, before long, workers in our own country will be contributing to the record of experience with the new remedy.

Of interest in the same connexion is the brief account (at page 12) by Winter and Smith, working in the Biochemical Laboratory at Cambridge under Professor F. G. Hopkins, F.R.S., of some very suggestive observations, which give the first hint available as to the mechanism of the action of insulin and its relation to the glycogenic function of the liver. Their observations appear to indicate that the glucose of the normal blood is not the ordinary  $\alpha$ - $\beta$  glucose, but the unstable form known as  $\gamma$  glucose, which has never yet been isolated in the free condition. They find indications of the conversion of  $\alpha$ - $\beta$  glucose into the unstable  $\gamma$  form by a liver extract when activated by insulin, which seems to play the part of a co-enzyme. The confirmation and extension of these observations will be awaited with great interest; even a small step towards a scientific understanding of a condition like diabetes may well entail a sweeping advance in practical treatment.

At the present time no insulin is available in this country. The method of preparation on a commercial scale is under intensive investigation in the laboratories of the Medical Research Council, and there is reason to hope that within a few months a sufficient supply may be obtained for careful test in hospitals. It is, of course, essential that the preparation should be free from bacterial contamination, and it will be observed from the paper by Banting and his colleagues published this week that the clinical administration of a pure

product calls for very careful management. The details they have set out will, we have no doubt, be studied by practitioners in expectation of the time when adequate supplies become available.

### PSYCHO-ANALYSIS.

THE discussion of psycho-analysis, which has been carried on in our columns for several months, has, we think, served a useful purpose. The profession have had the advantage of reading many clearly expressed opinions entertained by men eminent in various special departments of medical science upon a subject of general interest. These opinions have been widely divergent, but they have been expressed without the personal bitterness which has often made such discussions distasteful to fair-minded men. We think, however, that the last word in this particular discussion may fitly be left to Professor G. M. Robertson, whose thoughtful letter is printed in this issue. We do not, of course, take upon ourselves to pronounce judgement upon the issues, but we may be allowed to say that the concluding paragraph of Professor Robertson's letter seems to us to enunciate a thoroughly sound doctrine. We do not mean, and we do not suppose that Professor Robertson means, that no useful opinion upon the principles of psycho-analysis can be formed save by the small minority of the profession who are able to employ technical clinical methods based on these principles in the actual treatment of many patients. But, as we indicated some weeks ago, a scientific testing of some of the psycho-analytical principles is within the power of us all.

The reason why so little of such testing has been done is easy to see. Any reader of Freud's Introductory Lectures or of his *Traumdeutung*—which are, we suppose, the first of his works likely to be studied—will experience numerous temptations to digress into that verbal dialectic which is the bane of discussions of psycho-analysis in general and Freud's theory of dreams in particular, a logomachy from which even our recent correspondents have not been altogether immune. The interpretation of particular dreams is so delectable, so reminiscent of the triumphs of Mr. Sherlock Holmes, that one is led to doubt whether the eminent author is playing us quite fair. One wonders, for instance, whether the dream of the father who appeared repeating the quarters of the hour is really better interpreted by the pun of *Urmensch* and *Uhrmensch* than by the dreamer's prosaic first association.<sup>1</sup> Then again the explanation of dream symbolism by analogy with primitive forms of language inevitably raises the venerable but no longer venerated ghost of Paley.

But if these temptations are resisted it will be found that Freud not only suggests but urges upon us many subjects for direct investigation, which need no elaborate apparatus nor access to psycho-pathological material. We may take as an example his comment on a paper published by Pözl in 1917. This investigator, compared the immediate reproduction of certain visual stimuli with the reproduced contents of the dreams of the subjects in the night following the experiment. Freud comments in the following terms: "It appeared, then, unmistakably that details of the picture exhibited to the subject of the experiment and not noticed by him (*nicht von der Versuchsperson aufgefassten Einzelheiten*) provided material for the dream activity (*Traumarbeit*), while the details consciously perceived and recorded in a drawing after the experiment did not reappear in the manifest content of the dream. The material assimilated by the dream activity was by it utilized in the well-known 'arbitrary'—more properly, self-controlling—way

for the service of the dream-building tendencies. The suggestions of Pözl's research go beyond the scope of dream interpretation as investigated in this book. Briefly, however, one may note how far removed this new method of experimentally studying the formation of dreams is from that crude technique which consisted in the introduction into the dream content of sleep-disturbing stimuli."<sup>2</sup> This is but one example of the many possibilities which Freud's work suggests of experimental work, testing fundamental points of the general theory, which all who choose can perform. We note that Mr. Whateley Smith has recently<sup>3</sup> applied experimental and statistical methods to the testing of the value of Jung's word-association method and to the psycho-galvanic reflex. The psycho-galvanometer is not an instrument available to many, but an experimental and statistical investigation of the word-association test can be carried out without access to a psychological laboratory; indeed the statistical methods of Jung himself leave much to be desired. There is, in fact, a wide range of psychological phenomena within the compass of the normal which anyone can study, and, by studying, both add to knowledge and entitle himself to form and express an opinion upon what is, whether for good or evil, a remarkable movement in psychological medicine. Freud himself insists upon the duty of making such investigations, and tells his elementary students that dreams and slips of the tongue, etc., are material which they can study as well as he can—"the phenomena are not strange, you have or may easily acquire as much experience of them as I have myself." But not unreasonably he declines to admit the pretensions of the man in the street, or even the man in the consulting room, to sit in judgement upon technical clinico-pathological developments of principles which the critic has never investigated at all. In any other branch of medical science this distinction would be regarded as self-evident. A man whose physiological training consists of an elementary course of undergraduate instruction perhaps twenty years ago does not presume to controvert the opinions of a Sherrington or a Haldane. Were it an unwritten law that none should either publish books or even write letters upon psycho-analysis unless they had themselves executed a piece of research, however humble, within the field of normal psychology, a healthier professional opinion on the whole matter would be created, and we should soon know whether our generation has witnessed the discovery of a great truth or the exploitation of a gigantic error.

### THE CENTENARY OF JENNER'S DEATH.

THE centenary of the death of Edward Jenner, the discoverer of vaccination, will be commemorated in Paris and in London. Jenner was born at Berkeley, in Gloucestershire, where his father was vicar, on May 17th, 1749, and, after a life of varied activity, died there on January 26th, 1823. On Tuesday, January 23rd, the Académie de Médecine of Paris will hold a meeting in honour of Jenner, and on Friday, January 26th, there will be a special meeting of the Royal Society of Medicine, under the chairmanship of the President, Sir William Hale-White, at 8.30 p.m., with the same object; an address on Jenner's life and work will be given, and objects of historical interest will be shown. An exhibition of personal relics of Jenner—pictures, engravings, manuscripts, books, caricatures, etc.—will be open at the Historical Medical Museum, 54a, Wigmore Street, on January 26th, and will remain open for some months. Jenner performed vaccination for the first time on May 14th, 1796. The subject was a boy, about 8 years old, named James Phipps, and the vaccine matter was taken from

<sup>1</sup> *Vorlesungen zur Einführung in die Psychoanalyse*, fourth edition, pp. 264-265.

<sup>2</sup> *Die Traumdeutung*, seventh edition, p. 127 (footnote).

<sup>3</sup> *The Measurement of Emotion*. London: Kegan Paul, 1922.

the hand of Sarah Nelmes, a dairymaid, who had become infected by her master's cows. On July 1st Jenner inoculated the boy with variolous matter taken directly from a pustule, but no disease followed. He wrote to his friend Gardner at once. "The boy," he said, "has since been inoculated for the small-pox, which, as I ventured to predict, produced no effect. I shall now pursue my experiments with redoubled ardour." The possibility had been present in the mind of Jenner for a good many years. He began his professional education under Mr. Daniel Ludlow, of Sodbury, Gloucestershire, when only 13 years of age. He became a house pupil of John Hunter at St. George's Hospital in 1770. While at Sodbury Jenner learnt that there was a popular belief that a person who had had cow-pox could not take small-pox, and when, on leaving St. George's Hospital, he went back to Berkeley, he found that the belief was general among the milkers in and around that small town. It was not until 1788 that he brought his hypothesis that inoculation with cow-pox would prevent small-pox before the profession in London, and it was not until 1796, as we have said, that he ventured to put it to the test. Henry Cline, surgeon to St. Thomas's Hospital, who seems to have been one of the few people impressed by Jenner's statement in 1788, was probably the first person to perform vaccination in London. In August, 1798, he wrote to Jenner: "The cow-pox experiment has succeeded admirably. The child sickened on the seventh day; and the fever, which was moderate, subsided on the eleventh day. . . . I have since inoculated him with small-pox matter in three places, which were slightly inflamed on the third day, and then subsided." It was in 1798 that Jenner published his famous "Inquiry into the Causes and Effects of the Variolae Vaccinae, a Disease discovered in some of the Western Counties of England, particularly Gloucestershire, and known by the name of Cow-pox." A second edition was published in 1800, and a third, with some additions, in 1801. The "Inquiry" was also published in America, and was translated into Latin and into nearly every European language. A special Jenner Centenary Number of the BRITISH MEDICAL JOURNAL was published on May 23rd, 1896, to commemorate the one-hundredth anniversary of the first vaccination. The issue contained a biography of Jenner, a number of articles on cow pox, vaccination, and small-pox, and a remarkable set of coloured drawings made by Kirtland in 1802, showing side by side the development, from the second day to the sixteenth, of the pock produced by the inoculation of small-pox and by the inoculation of cow-pox. The contrast after the fifth day is very striking, and so far as we are aware no similar series has ever been published, nor is it likely that it will ever again be possible to produce such a set of drawings from nature. On July 5th, 1902, a special Vaccination Number of the JOURNAL was issued, reproducing the biography above mentioned, and containing a series of authoritative communications on small-pox and vaccination, together with coloured plates and other illustrations, contrasting the eruptions of chicken-pox and small-pox, and depicting the local course of vaccination with calf lymph.

#### THE WORKS OF PASTEUR.

PASTEUR usually reported the results of his work to scientific or medical societies, and his papers are scattered through the transactions and proceedings of these societies and in reviews and journals. He produced only two books—one on beer and the other on disease in silkworms. His grandson, Dr. Pasteur Valléry Radot, has undertaken to edit a complete collection of all his grandfather's writings; it will be issued in seven volumes by the firm of Masson of Paris. The papers will be classified under six heads, which mark the stages of Pasteur's scientific development. Two volumes have already appeared. They make a very handsome appearance in large octavo (8° jésus), and the frontispiece of the first is a well-known portrait of Pasteur in his laboratory, by A. Edelfelt. This volume contains the articles on molecular dissymmetry (50 francs), and the second those on fermentation and so-called spontaneous generation (65 francs). The other papers will be arranged in four classes—his studies of

vinegar and of wine, of diseases in silkworms, his inquiries into the manufacture of beer, and his investigations of virulent diseases and virus vaccines. The seventh volume will consist of miscellaneous scientific and literary articles. A few hitherto unpublished papers will be included. The articles will be arranged in chronological order under these several heads. The text is being produced without alteration, but a large number of notes are being added. The editor in his preface says that the articles, lectures, and memoirs brought together in these volumes show both the immensity and the unity of Pasteur's work. By a chain of facts, reasoning, and experiment Pasteur was led from molecular dissymmetry to the fermentations, then to a study of so-called spontaneous generation, and finally to the investigation of transmissible diseases, to virus vaccines, and to the prophylaxis of rabies. We may take this opportunity of complimenting our contemporary *Nature* on the excellent Pasteur Supplement which it published on December 23rd; it is illustrated by a portrait of Pasteur and a photograph of the statue at the Sorbonne, Paris. It contains an introductory article by Mr. Stephen Paget, a masterly review of the influence of Pasteur on the development of bacteriology and the doctrines of infection and immunity by Professor William Bulloch, F.R.S., and another on Pasteur and preventive medicine by Professor J. C. G. Ledingham, F.R.S. The French illustrated paper *L'Illustration* has published a fine supplement containing beautiful illustrations, including portraits of Pasteur at various ages, and a coloured drawing of the crypt of the Institut in Paris, where he is buried.

#### THE CENTENARY OF THE "LANCET."

THE *Lancet* has entered upon its centennial year, for its first number was published on October 5th, 1823. The prospectus stated that the primary object of the founder was to convey to the public and to distant practitioners, as well as to students, reports of the metropolitan hospital lectures and to describe all important cases that might occur in England or elsewhere. Not satisfied with this comprehensive programme the editor assured his future subscribers that he would be indefatigable in making his paper a complete chronicle of current literature. Another purpose, not announced, but disclosed even in the first number, was to support the political party to which the editor belonged. The first number in its original form consisted of thirty-six small octavo pages, so that the space the editor allowed himself to carry out his rather grandiose intentions was limited. He kept his promise about the lectures, for the first number contained a report of one given by Sir Astley Cooper, and to keep the balance true there was inserted an extract from the *London Medical Repository* in which Mr. Henry Earle, assistant surgeon to St. Bartholomew's Hospital, developed a controversy with Cooper as to whether fracture of the neck of the thigh-bone ever united, and whether Cooper had said that Earle was maintaining the contrary view in order to depreciate Guy's Hospital and its teaching; for Cooper, while lecturer at St. Thomas's Hospital, was surgeon to Guy's Hospital. Those who have read Sir Squire Sprigge's biography of his great predecessor will know that Thomas Wakley was a man of volcanic energy, not very heavily weighted with scruples, and not at all afraid of the law of libel. He was in fact involved in a group of libel actions which dragged on some ten years, but in most of them he won actual or moral verdicts, for the abuses he denounced were real, though the manner of his denunciation was often unnecessarily violent. The *Lancet* under Wakley's direction had a great part in the reform of medical education, in the abolition of the nepotism which had governed the selection of hospital staffs, and generally in raising the standard of knowledge of the medical practitioner in England. His criticisms, destructive and constructive, were among the most important elements in the formation of the public and professional opinion which resulted in the passage of the Medical Act in 1858 setting up the *Medical Register*. Among the other abuses he attacked in the public interest were the defective

organization and administration of workhouse infirmaries and the evils of quack medicines. A point of perhaps rather technical interest is that the form of make-up of a general medical journal which Wakley evolved—the publication of original articles, of reports of societies, of reviews, of editorial comments on medical occurrences, pathological, social, and political—has been very generally imitated by other medical journals in this country, in America, and in Germany. The influence of the *Lancet* has been very great and very beneficial, and it may, we hope, continue to prosper along the lines which have established and maintained its reputation with the medical profession.

#### DUCHENNE OF BOULOGNE.

A CORRESPONDENT has forwarded to us the following notes from an old diary: One summer morning in the year 1860, about 7.30 a.m., in the Hôtel-Dieu, Tuckwell of Oxford and I were awaiting our master, Trousseau. As in his genial way he entered the ward, we saw behind him a little, quick, wiry, vigilant man, whom Trousseau introduced to us as Duchenne of Boulogne. Duchenne had no post in the hospital, but Trousseau, in his sympathetic and ardent way of welcoming any scientific brother, having discovered Duchenne, carried him into his wards to help him in his own researches and also to give Duchenne a large field for his energy and talents. Trousseau, whose courtesy to his English pupils was well known, had been very friendly to me, and thus it was that I became intimate with Duchenne. He invited me to his clinic, which at that time was a remarkable crowd. How it was gathered together and maintained I cannot say. I have no recollection of any assistant, or at any rate none of any quality. His apartment consisted of two or three narrow rooms in the mountainous top of a building in the Boulevard des Capucins. How on earth, in those days of no lifts, day by day this oncourse of cripples from every department of France lumbered up to these consulting rooms I cannot imagine. Perhaps the busy clicking and other more aggressive properties of his electric apparatus, to which the sanguine little man attributed even more virtue than has since been realized, had their ascination. Indeed these machines had much in character with their lively, impulsive and nimble-minded master. At his time of his life I suppose, from the motley groups I saw in his clinic, his practice was mainly gratuitous. In his ardent desire for knowledge Duchenne did not make money his first consideration. He cordially invited me to attend his clinic and never alluded to any fee, invaluable as that experience was. It was wonderful to watch the unravelling under his penetrating eye of the several kinds of disease of nerve and muscle as he discriminated them, or described them anew. It was a rare lesson in clinical insight and in apprehension of our ignorance. But my purpose at present is only to recall some of the personal qualities of that great clinical discoverer. In after years I saw much of Duchenne, chiefly in Paris; but once or twice he was tempted over to England. His chief visit was, if I remember right, at an annual meeting of the British Medical Association, when, by Hughlings Jackson, Lockhart Clarke, Buzzard, G. H. Lewis, and myself, he was tempted to cross the Channel. Duchenne, a child in travel, started from home with a trunk which may have held a few small pieces of raiment, but chiefly a collection of bones from a few of his autopsies. This baggage, as his manner was, he lost *en route*, and arrived in London in much agitation about his missing specimens, a distress which became almost frenzy when we warned him of the hubbub which would arise on the official investigation of his trunk. It so happened that about that time certain human remains in a carpet bag, supposed to be the relics of a gruesome murder, had been dropped into the Thames. Happily his trunk was returned to him intact, and he was able to demonstrate his bones with joy. Duchenne had that childlike nature which often comes with genius: insight, earnestness, ardour, enthusiasm, simplicity; he deserves to be remembered by neurologists as one of the great pioneers of his day.—C. A.

#### A PREDISPOSITION TO MINERS' NYSTAGMUS.

A PAPER on miners' nystagmus, which Mr. A. S. Percival of Newcastle-on-Tyne communicated to the Oxford Ophthalmological Congress, expresses some dissatisfaction with the recent findings of the Departmental Committee which reported on this disease. Mr. Percival holds that the one and only conclusive factor in the production of the disease is working in a bad light, but he recalls some of the work of the late Mr. Simon Snell, who concluded that working in a bad position was also a factor. The main point of Mr. Percival's communication, however, is to maintain that there is a congenital predisposition to the disease. He believes that the disease is only likely to affect those who have some primary deficiency in the "light fixation centre," and that there is as much diversity in the activity of this centre as there is in the control of binocular fixation. He writes: Some "5 per cent. of all children born have a predisposition to the disease [miners' nystagmus], and if they have not this predisposition they will never acquire it. If they have this predisposition they have it for life. Unfortunately no means have yet been discovered for recognizing the predisposition before the onset of the disease." The practical bearing of this theory lies in the application of the Workmen's Compensation Act. He contends that it is fundamentally unjust. "Practically it means that the patient receives whole or part compensation for the rest of his life, for there are very few workmen who are wise enough to seek other employment. It is bad for the workman pecuniarily, for whatever his ability in other ways he can never make much money, even with part compensation, while doing light jobs at bank. . . . It is obvious that the unfortunate pitman who acquires miners' nystagmus must be given compensation for a limited period, say twelve months or so, while recovering from his symptoms, and to give him time to obtain other employment, but that he should never be allowed to obtain underground work again." Mr. Percival states that he has had four cases of workmen who have acquired and reacquired miners' nystagmus three or four times—getting relief, returning to the pits, and again obtaining compensation. Such experiences as these certainly support the recommendation that a man once affected by the disease should be definitely debarred from coal mining once and for all. The theory of predisposition was noticed in the report of the Miners' Nystagmus Committee, which drew attention to the work of Ohm; but even this worker failed to discover any practical plan for sifting out the predisposed, and had to conclude, "I can only add my voice to this cry for 'More Light' in the mines." The magnitude of the problem is shown by a recent reply on behalf of the Home Office to a question in the House of Commons. It was stated that the total number of workmen in receipt of compensation for nystagmus was 6,449 in 1919, 7,928 in 1920, and 6,717 in 1921; statistics were not collected for 1918. The first report of the expert committee of inquiry into the causes of nystagmus set up by the Medical Research Council in 1920 was published early in 1922, and the committee is still at work.

#### THE RHODESIAN TESTS OF BAYER "205."

In the *Deutsch-medizinische Wochenschrift* for December 22nd, 1922, there is a report by Professor F. K. Kleine and Dr. W. Fischer on the inquiry they conducted in Rhodesia into the action of Bayer "205" in trypanosomiasis. Three lines of investigation were followed: What therapeutic effect does the drug have (a) on infected human beings, (b) on infected cattle, and in what measure is it effective as a prophylactic of trypanosome diseases in man and beast? A fourth question to which an answer was sought was: Can an infected fly be sterilized by being fed on an animal given "205"? To this last question the answer appears to be in the negative. It was found that the proportion of infected tsetse flies was small, and even when they were artificially fed on infected animals most of the flies escaped infection. The trypanosomes investigated were *T. brucei*, *T. rhodesiense*, *T. bovis* (which is possibly identical with *T. vivax* and *T. caualbus*), and *T. caprae*. More than 180 monkeys (*Cercopithecus rufovir*)

were employed, as they are very susceptible to infection with *T. brucei* when not living in freedom. It was found that when 0.25 gram of "205" was given by the mouth (stomach tube) the organisms (*T. brucei* and *T. rhodesiense*) disappeared from the blood in forty-eight hours. In some cases a single dose was sufficient to effect a cure, but of seven monkeys given 0.25 on two consecutive days three relapsed. Seven other monkeys given 0.25 gram on each of three or four consecutive days showed no sign of relapse during an observation period of about four months. The subcutaneous administration of the drug was considerably more effective than the oral; after the subcutaneous injection of 0.05 to 0.15 gram not one of the twenty-seven monkeys showed a relapse, and the injection was followed by the disappearance of the trypanosomes from the blood within twenty-four hours. The superiority of the subcutaneous over the oral route was still more marked when prophylaxis was the object. Given by the mouth "205" prevented infection only for two to four days, whereas when given by subcutaneous injection two months' immunity was conferred; the explanation suggested is that the subcutaneous route provides the body with a *dépôt* which is slowly eliminated. When the oral administration of the drug to a healthy monkey was followed in a few days by exposure to infection an abortive form of the disease sometimes developed; though organisms were not demonstrable in the blood, the monkeys were at least comparatively immune to subsequent infection and this immunity must have been active, as the passive immunity conferred by the oral administration of the drug lasts only a few days. Resort to this active immunization is, however, in the opinion of Professor Kleine and Dr. Fischer, not likely to be very successful. They found that the organisms soon become resistant to the drug if the dose was too small, and they confess that their therapeutic experiments were less successful with cattle than with monkeys. Their detailed report on six cases in man is very encouraging; and they recommend subcutaneous or intravenous injections of 1 to 1.5 grams repeated once or twice at moderate intervals. This is a big dose, but it is urgently indicated on account of the risk, already referred to, of the organisms losing their susceptibility to the drug when it is given in small doses.

#### ATMOSPHERIC CONDITIONS AND INDUSTRIAL EFFICIENCY.

Two reports have just been issued by the Industrial Fatigue Research Board, and it may be said that the main conclusions of each of them relate to the influence of atmospheric conditions on the efficiency, and presumably therefore on the health, of two large classes of industrial workers. In Report No. 20 Mr. H. C. Weston describes his observations on efficiency in fine linen weaving. The weaving of fine linen is one of the most trying industrial operations known in this country, as it has to be carried on in a hot and very moist atmosphere, in order to reduce the breakages of the yarn to a minimum. Owing to artificial humidification, the wet and dry bulb temperatures of the air in the sheds seldom differ by more than 2° F., and the actual temperature often exceeds 70°. Mr. Weston made hourly observations on the rate of production of forty looms in each of two sheds for periods of four or five months, and as the temperatures were observed at the same time, he was able to obtain accurate information concerning efficiency (as indicated by output) in relation to temperature. He confirmed the already well-established fact that within certain limits the higher the temperature the greater the quantity of linen woven, but he found that at temperatures above 73° (wet bulb) the relation no longer held. The high temperatures caused such discomfort and fatigue in the weavers that their productivity fell off, and it might become distinctly less than that observed at lower temperatures, in spite of the more favourable physical conditions for weaving. Other evidences of fatigue were obtained by comparing the rate of production in the morning and afternoon. Due allowance being made for the temperature effect, it was found that when the

workers were on a nine-hour day their afternoon production rate was 8 per cent. less than the morning rate. When on an eight-hour day it was only 4 per cent. less, but when on a seven-hour day it was 3 per cent. more than in the morning. Again, the rate of production is greatly affected by illumination, and with artificial lighting the output was 11 per cent. less than with natural lighting. In Report No. 22 Miss May Smith describes some results of her study in the laundry trade. This trade is a difficult one to investigate, for even in the largest laundries the workers are not often kept on exactly the same class of work for more than a few hours at a time, so that variations of output are not easily ascertained. Still, Miss Smith was able to show that the efficiency of women employed in ironing shirts, in smoothing by means of presses and calenders, and in other work, is usually lower in the afternoon than in the morning, and falls off especially towards the end of the afternoon. Still greater reductions of efficiency were observed when the women were put on to a ten-hour day instead of the usual nine-hour day. Such fatigue effects are not to be wondered at, because of the adverse atmospheric conditions. Observations made in twenty-two laundries showed that the temperature near the hand-ironing and calender tables was frequently over 80°, and on hot days was well over 90°, whilst the cooling power of the air (investigated by means of the kata-thermometer) fell to 2 or even to 1. It is well known that, for reasonable comfort, this cooling power ought to exceed a value of 6, but only 12 per cent. of all the observations attained this standard. Supposing that the heat derived from the laundry apparatus is unavoidable, then the cooling power of the air ought to be increased by greater ventilation, and yet it was found that the air currents in the laundries were not, as a rule, much greater than those observed in the factories of an industry such as that of boot and shoe manufacture, which has no hot processes. Hence it is highly important that the investigation of atmospheric conditions in laundries should be widely extended, and the employers made to realize that they must so control their plant, or control their ventilation, that these excessively low cooling powers are avoided.

#### OCTOCENTENARY OF BART'S.

ST. BARTHOLOMEW'S HOSPITAL celebrates this year its octocentenary, for it was in 1123 that Rahere founded it upon its present site. In our issue of February 4th, 1922, we recorded the holding of a meeting at the Mansion House to make preliminary plans. The provisional programme for the 800th anniversary celebrations is published in the current issue of the *St. Bartholomew's Hospital Journal*. The days chosen are Tuesday, Wednesday, and Thursday, June 5th, 6th, and 7th; these three days have been definitely fixed upon, though the precise events of each are subject to alteration. According to present arrangements the celebrations will begin with service at the Priory Church of St. Bartholomew-the-Great, followed by luncheon to the delegates from medical schools in the British Empire and from American schools, and the reception by the Prince of Wales, President of the hospital, of addresses from the delegates; in the evening an old students' dinner will be held. On the second and third days "Bartholomew Fair" will be held within the hospital precincts; there will be a reception at the Royal College of Surgeons, a *conversazione*, a banquet to the delegates, and a service at St. Paul's Cathedral. During the celebrations an historical and scientific exhibition will be held within the hospital.

We understand that the Royal Society of Medicine intends to celebrate the centenary of Pasteur by a meeting next month. On Friday, February 2nd, a dinner will be held at Vintners' Hall, when the French Ambassador will be in the chair, and the guest of the evening will be Dr. Pasteur Valléry-Radot, Médecin des Hôpitaux de Paris, Pasteur's grandson. Tickets, two guineas (inclusive), can be obtained from M. André Simon, 24, Mark Lane, E.C.3.

## Louis Pasteur.

[FROM OUR PARIS CORRESPONDENT.]

"The greatest charity we can show to the dead," said Pascal, "is to act towards them exactly as they would have wished us to have acted while yet they lived."

We have just been celebrating the hundredth anniversary (December 27th) of the birth of Pasteur. How limited are our means of offering due homage to such a man! The bells of France have rung in his honour. The faithful in pious pilgrimage have assembled at his humble birthplace in Dôle. Strasbourg and Lille have celebrated the sojourn of the master within their universities. Lastly, Paris, the heart of France, has stood in meditation before his tomb, where a simple name more eloquent than all epitaphs is inscribed.

And we have had speeches! It is here that the thought of Pascal obtrudes upon the mind, and one wonders what Pasteur would have made of this flood of words—he, the silent worker who never left his laboratory except to oppose to impassioned arguments sober language and the final verdict of the facts of experiment. Recall the famous debates in the Academy of Medicine. Hardly could that illustrious assembly forgive a chemist, a layman, for daring to tread the path reserved for clinical medicine. The Academy was bitterly reproached for its attitude, but let us note that these discussions would not have taken place at all if the Academy had not first done itself honour in inviting Pasteur to take his place in its ranks. The medical profession could hardly extricate itself from the language of metaphysics, while its fiery adversary spoke the language of experiment. For Pasteur, a man who made an ill-conceived experiment or indulged in false reasoning was capable of anything. Dr. Roux tells a story of the delightful simplicity of his master, who, after having read a work which appeared to him particularly bad, cried in his exasperation, "I should not be surprised if a man who writes things like that beats his wife!" As though to beat one's wife were the depths of scientific depravity.

This same Academy consecrated its meeting of December 26th, 1922, to the memory of Pasteur. It was a fine meeting; the leaders of the profession came in turn to bow before the master. It was a cascade of oratory—a little prolonged, no doubt, but deeply moving. President Behal sketched with bold strokes the career of Pasteur. Then Professor Delezenne spoke for biology, Professor Vidal for medicine, and Professor Delbet for surgery. Wallich, Barrier, and Calmette described his influence on obstetrics, on veterinary medicine, and on hygiene. The mere enumeration is eloquent.

From a field so wide let us glean a few grains. In 1871 Pasteur wished to visit a great English brewery. He was received in England as a leader of French science. He did not spend much time in talking to the managers. He examined all the specimens of beer microscopically and picked out those which were going to be spoiled. A week afterwards he returned to France; the brewery had bought a microscope, and all the yeasts had been changed.

He meditated incessantly on the work of Jenner, and was himself an actual link between those two benefactors of humanity, Jenner and Lord Lister. By Lister he was connected with Simpson of Edinburgh, and with Semmelweis of Vienna.

Behal drew a picture of a very human Pasteur. He did not show him to us marked from his birth with a star on his forehead. He was not a particularly brilliant student—"He is not at all a genius." On the other hand, the orator who succeeded him, Vidal, said, "He appears to us like one of those providential beings that Nature sometimes creates to renew abruptly the orientations of science. He was served by a spirit of divination. But that is not the whole secret of his genius . . ."

Of these two conceptions the first is the more encouraging, and Pasteur is only the greater if it be true that, far from being one of the predestined, he was the child of his work, of his method, and of his will. It is not necessary for us little people to descry an impassable abyss between our minds

and his. Let us realize that if we see him on a lofty peak it is not an inaccessible Everest. And yet! . . . What seems the most genuinely moving trait of genius in Pasteur is the flash of his thought, which passes from physical chemistry to biology in studying the constitution of the racemates. A splendid cerebral reflex involving prodigious consequences: Pasteur for a moment embodied the intellect of man.

I shall take no great risk if I attempt to reconcile the two conceptions by regarding Pasteur in a light which seems to have escaped the attention of the orators. Pasteur was an artist. He had the artist's gifts, the artist's imagination. He soars above concrete experience. Looking on the picture presented by the formation of a crystal, Pasteur, though not yet a biologist, asked himself whether the healing of wounds might not be compared with this phenomenon. During his study of the diseases of beer he proved that they were caused by microbes. At once his imagination took wing: might not the same be true of the diseases of man? Scientist, he would have stopped at experimental facts; artist, he cast his line over the unknown. Pasteur the artist . . . Some day, perhaps, we shall return to this subject.

After the academic discourse of Vidal comes Delbet, full of fire; he has no written speech, but, as becomes a surgeon, handles words as he would handle a knife—neatly, incisively, brilliantly. He shows in bold outline the struggle of Pasteur against the theorists of spontaneous generation; the coming of the autoclave; the part played by Lister; the difficulties of Lucas-Championnière in introducing to Paris the principles of Edinburgh; the frightful mortality of the surgical wards before the sixties; the discovery of vaccines; serotherapy; the dawn of bacteriotherapy.

With Wallich we come to the most simple and the most persuasive form of eloquence—that of figures. It was much appreciated. What maternity meant before and after Pasteur, such was his theme. "May the memory of Pasteur receive this day the homage from all mothers!"

Calmette spoke last. He recalled the figures of Copeland of New York: "Where two persons out of a thousand died fifty years ago, in 1920 only one dies." He deplored the fact that in hygiene the theory of infection, the idea of which was expressed for the first time in 1876 in the Public Health Act, was not accepted in France until 1902. "We cannot but regret," he said, "that the country of Pasteur was not the first to profit by the beneficent consequences of his work."

A second gathering, more intimate, more poignant, was held on December 27th at the Institut Pasteur. It is well known that Louis Pasteur sleeps within the crypt of the building, a holy sepulchre worthy of him. The laboratories of the Institut raise towards heaven their perpetual intercession, and the fervent spirit of scientific research mounts guard of honour above the tomb. The President of the Republic came to bow before the great dead, while Parliament rendered respectful homage by imposing upon itself the sacrifice of five minutes' silence. At the Institut we had a series of nineteen speeches . . . but do not be alarmed—they lasted only ninety minutes altogether. Alas, that no other manner of honouring Pasteur could be thought of. The idea was to ask a representative of each of the societies to which Pasteur had belonged to speak. Yet this series of brief testimonies was impressive. The secretary of the Academy of Medicine, Professor Achard, made the *amende honorable* for its early opposition. "He has taught us much, and"—lowering his voice—"to be humble."

The speeches over, the guests bowed reverently before the tomb of the master. It seemed as though we were present at the birth of a new cult—a divine cult of a deity from which nothing was lacking, not even miracles. . . . That was the impression produced once again by the ceremony at the Sorbonne on the evening of the 27th, when we had the happiness of seeing delegations of students, not only French, but foreign. Thus did the great Frenchman soar above the boundaries—the artificial divisions which have no part in the domain of science.

Ring out, bells of Dôle! The centenary we have just been celebrating is one of the great dates in the history of the world. And to give an example of that "great charity" of which Pascal spoke, let us honour Pasteur by putting into practice the counsel he gave in such simple terms: "Again I tell you—work."

## England and Wales.

### THE NEWCASTLE MEDICAL INSTITUTE: DR. J. W. SMITH'S PORTRAIT.

ON December 20th, 1922, a very interesting and enjoyable evening was spent at the monthly supper, when the presentation was made of the portrait of Dr. J. W. Smith, the donor of the institute. The portrait was painted by Mr. Hodgson Campbell of Newcastle, and was the gift of members of the Institute, and also of many other medical friends in the United Kingdom. Dr. James Don presided. Professor David Drummond, who made the presentation, referred in very appreciative terms to Dr. Smith, his services to the profession, and his gift, and remarked that coming generations of medical men, though they had never had the privilege of knowing him, would value all that had been done for them, and would be able to form some estimate of the qualities of their benefactor, who was respected and loved by patients, and esteemed and honoured by practitioners. Professor Drummond's speech was followed by the enthusiastic singing of "For he's a jolly good fellow." Dr. Smith, in accepting the gift, said he was very much touched by the kindly words of Professor Drummond, and the way in which those present had endorsed them. He thanked them most heartily. To have the honour and respect of one's fellow medical men was indeed something to be proud of, and he knew that this gift was but an expression of these sentiments. He begged Dr. Bolam, a friend of many years, to accept it for the Institute on behalf of the members, and asked him to accept also an enlarged photograph of his son, the late Dr. James Wilkie Smith, to whom the Institute was a memorial. Dr. Bolam in accepting these gifts, and thanking Dr. Smith, alluded to his enthusiasm in all matters pertaining to the welfare of the profession, and to the fact that for many years he had been a Representative at the Annual Meetings of the British Medical Association.

### UNQUALIFIED MIDWIFERY PRACTICE.

At a special meeting of the Central Midwives Board for England and Wales held on December 20th, 1922, Sir Francis Champneys presiding, two of the cases were dismissed and three midwives were removed from the roll. The ordinary monthly meeting was held next day. A letter was read from the secretary of the Royal Sanitary Institute urging that action should be taken by amending Section 1 Subsection (2) of the Midwives Act, 1902, or otherwise, in order to prevent unqualified persons from attending women in childbirth without the effective direction of a qualified medical practitioner. In connexion with this letter a resolution of the County Councils Association was considered to the effect that Section 1 (2) of the Midwives Act, 1902, should be amended so as to ensure that in no case, save an unpreventable emergency, shall an uncertified woman, for gain, attend women in childbirth otherwise than under the direct physical supervision of a qualified medical practitioner. It was agreed to reply that in the opinion of the Board the words "under the direction of" in Section 1 (2) of the Midwives Act, 1902, mean "in the presence and under the direction of." The Section also includes the words "habitually and for gain," which, in the Board's opinion, are unnecessary, lead to confusion, and generally render the Section futile. The Board will take the earliest opportunity of pressing for the necessary amendments.

### SCHOOL MEDICAL TREATMENT IN LONDON.

The London County Council has decided on the arrangements for the year 1923-24 for the medical and dental treatment of children attending the elementary schools. Three new dental centres are to be opened in 1923, and it is hoped that suitable premises will be secured for three others which have been authorized. It is hoped also that four new centres for the treatment of minor ailments will be opened early in the year. The present arrangements for the treatment of eye defects provide for 33,750 cases a year; it is proposed to increase this total provision by 900. A class conducted for children suffering from squint is to be continued. The proposals for the treatment of ear, nose, and throat cases for the ensuing year will enable 12,850 cases to be dealt with, as compared with 17,030 cases in 1922-23. There has been a falling off in the number of children sent for operative treatment, partly because of recent statements in a section of the press, and partly because the tendency now is for surgeons not to

operate in slight cases. It is thought that the provision may safely be reduced by more than 4,000 cases. In-patient treatment for these cases is provided already at one centre, where the children are kept for two nights after the operations, and is shortly to be provided at a second. It is estimated that there will be a net reduction of 330 cases of ringworm to be dealt with. The special treatment of discharging ears by the ionization process has proved successful, and it is hoped that it may be started at one or two additional centres during the year. Three centres provide facilities for remedial exercises for children suffering from curvature of the spine. The Education Committee is considering whether the purpose of these centres could not be achieved in the remedial classes which have been formed in a number of schools. Remedial courses for stammering children are in operation at six centres and are to be continued. A reduction was made in the fees of doctors and dentists as from April 1st, 1922, and it is not proposed that any further reduction should be made at present. The estimated cost of the arrangements, apart from administrative charges, for 1923-24 is £85,425, a decrease of about £3,200 upon the expected expenditure for the current year.

## Scotland.

### SIR ROBERT PHILIP.

PROFESSOR SIR ROBERT PHILIP retired from the post of physician in charge of the special clinic for tuberculosis at Edinburgh Royal Infirmary on December 31st, 1922. At the meeting of the Royal Infirmary managers on December 18th, a special minute was adopted, on the motion of Dr. George Mackay, expressing the Board's deep appreciation of the very eminent services which Sir Robert Philip had rendered to the institution. He had been associated with it ever since 1882, when he became resident house-physician to the late Professor John Wyllie. In 1890 Sir Robert Philip was elected to the honorary staff as an assistant physician, and sixteen years later he became a full physician in charge of wards. In 1887, prior to his appointment to the infirmary honorary staff, he founded the first tuberculosis dispensary in the city, and his exertions and advocacy led later to the establishment of the Royal Victoria Hospital for Consumption. Since 1917 Sir Robert Philip has occupied the chair of tuberculosis in Edinburgh University, and in October, 1921, having completed fifteen years' service as full physician, the managers of the Royal Infirmary appointed him an extra physician with charge of a special clinic for tuberculosis. The time having come when the regulations debarred the appointment being renewed in its present form, the managers have invited Sir Robert Philip to join the consulting staff, and conferred upon him the title of physician consultant for tuberculosis, whereby his expert knowledge and advice might still be available, especially in connexion with the work of the tuberculosis out-patient clinic.

### MASSAGE ORGANIZATION IN SCOTLAND.

The first meeting of the recently constituted Scottish Board of the Chartered Society of Massage and Medical Gymnastics was held on December 11th, 1922, at the Western Infirmary, Glasgow, with Dr. J. Stuart Ross (Edinburgh) in the chair. Two subcommittees were appointed. One is to study the problem of providing an insurance scheme suitable for the needs of the Scottish members of the society, while the other is to study the local conditions under which the benefits of treatment by massage and allied methods may be made more available to patients, particularly those suffering from industrial injuries. Steps are also being taken to organize demonstrations to which the medical profession will be invited. The Board will meet quarterly in one of the larger cities in Scotland.

## India.

### NURSING AND CHILD WELFARE.

At a meeting at Delhi of the All-India Nursing Fund, Lady Reading reviewed the progress made towards an increase in the supply of Indian nurses, and emphasized the need for further financial assistance in pursuing a work which was so essential and urgent, in order to reduce the present high infant mortality in India. The meeting decided that in order to

attract Indian women of good education and position, the highest grades of the nursing profession should be opened to them. For that purpose two scholarships for post-graduate training in England are to be offered to Indian nurses. Application for scholarships should be sent to the honorary secretary, Lady Reading Nursing Fund, Delhi.

The Madras Child Welfare Association has arranged to start a school for the training of health workers in Madras. The Corporation has agreed to its child welfare centres being utilized for the training of health workers, and the superintendent of its child welfare scheme is undertaking the training.

#### ROCKEFELLER FELLOWSHIPS FOR INDIA.

The Indian Scientific Advisory Board, at the invitation of the International Health Board of the Rockefeller Foundation, has selected five Indian medical graduates, out of thirty-six candidates, to be the first holders of the fellowships allotted by the Foundation to India; they will pursue post-graduate studies in America. It is intended that each of the fellows should take up some special branch of medicine, and if at the end of the year the result justifies such a step they may be sent by the Foundation to England, or to some other European country, to extend their researches. The first five Indian fellows are a representative body, as they include two Hindus, one Sikh, one Mohammedan, and one Parsee. Their names are: Assistant-Surgeon Saranjan Khan, B.Sc., M.B., B.S.; C. R. Edibam, M.B., B.S.; H. G. Mathur, B.Sc., M.B., B.S.; Captain Sokhey, I.M.S.; and A. R. Mehta, M.B., B.S., D.P.H., D.T.M. and H.

#### UNQUALIFIED MEDICAL PRACTITIONERS IN BENGAL.

Of late years there has apparently been a considerable increase in the number of unqualified medical practitioners in Bengal, and particularly in Calcutta, and there was published recently in the *Englishman* an account of an interview on the subject with the Surgeon-General of Bengal, Lieutenant-General Deane. According to this article General Deane said that the Government could do nothing with the large army of quacks so long as they kept on the right side of the law; once they committed an offence, however, and were convicted, there was ample power to deal with the guilty person's freedom of practice. It could not be expected that the Government should allow only registered practitioners to practise, as there were so many "kavirajes" and other persons using indigenous systems. There was, in fact, no restriction on those who chose to follow the medical profession according to any system—Western, Ayurvedic, Unani, or homoeopathic—so long as they did not break the law either in the treatment of cases or in the supply of drugs. The Bengal Medical Act of 1914, which provided for the registration of duly qualified medical practitioners through the Bengal Council of Medical Registration, was working well. Registration was optional, but the Government intended eventually to make it compulsory.

#### RAT REPRESSION IN INDIA.

In a bulletin issued by the Agricultural Research Institute, Pusa, a plea is made for an organized attempt in India to deal with the rat pest, which is not only a danger to the health of the community, but causes much destruction of the food supplies. It is calculated that on the basis of an estimate of 800 million rats in India there is an annual loss of 9,125,000 maunds of grain, worth Rs. 45,62,50,000. A campaign for the extermination of rats by poison is suggested, but it is pointed out that to ensure success co-operation is essential among the people themselves, and between them and Government officials. Operations, to be successful, must be carried on over large areas and in an organized manner.

THE sixth Italian Congress of Industrial Medicine will be held at Venice in 1924, under the presidency of Professor Devoto of Milan, when the following subjects will be discussed: The effects of uniform and monotonous labour, introduced by Professors Cervidalli of Padua and Donaggio of Modena; Pre-natal assistance to healthy and sick mothers during pregnancy, introduced by Professors Ferroni of Florence and Devoto of Milan; Industrial poisoning through the respiratory tract, introduced by Professors Preti of Milan and Monti of Pavia, and Reduced hours of work for partially disabled workmen, introduced by Professors Pieraccini of Florence and Vitali of Venice. Professor Giglioli of Florence will review the recent progress in the pathology and hygiene of industry, and there will be a discussion on compulsory insurance in Italy and its results.

## Correspondence.

### PSYCHO-ANALYSIS.

SIR,—I hesitate to enter this controversy, but do so in the hope of throwing light on some misunderstandings and of making the issues simpler.

Dr. Steen, quoting Hart, is quite right in asking that "brain cells" and "ideas" be not confused or mixed. They belong to entirely different categories, and are best studied apart. This is, however, very different from saying that mental functions have not a physiological aspect. Dr. Steen is merely repeating a favourite text or maxim of that great neurologist and most profound and accurate thinker on the functions of the brain and nervous system, Dr. Hughlings Jackson. All who enjoyed the privilege of being taught by him will bear out the truth of the above observation, and those who wish to know why he laid such stress on this point will find the explanation in his classic writings.

The relationship between mind and matter is an unsolved problem. No one has bridged over the chasm that divides the two. But although no solution of this problem has yet been found, no physician, and certainly not Dr. Steen, denies that there exists a very important relationship between mental functions and the working of the cells and fibres of the brain. The onus of explaining this does not rest, however, on psycho-analysts. They are no more in default than all others who speculate on the mind and treat its disorders.

We all know that various physical conditions affect the life and the nutrition, and in consequence the functions of the cells and fibres of the nervous system. In the case of some of the simplest disorders of nerve function proof of this can be obtained. It is assumed, and with good reason too, that complex disorders of nerve function—namely, mental symptoms—are associated in an analogous way with affections of nerve cells and fibres. Materialistic investigations have, however, not led us very far, but fortunately mental symptoms have a psychic aspect as well as a physical one. Let me explain this by a very simple illustration.

I had a patient, a licensed grocer, who drank to excess and suffered from hallucinations of hearing. Why? The physiologist answers because the alcohol had poisoned the cells in his centre for hearing and affected their function. I next ask, Why did he suffer from these hallucinations when he was making out his bills? Why were the remarks heard always in the nature of complaints of overcharging? Why was he troubled by the voices of some of his customers only and not of others? The physiologist is now silent; the content of delusions and hallucinations is beyond his ken and his sphere; can he tell what language a man spoke when alive or what he said by examining Broca's convolution? The psychologist answers that the grocer is predisposed to receive hallucinations when he makes out his bills because, along with other factors, his conscience then reproaches him for dishonesty and he feels overcome by a guilty emotion. He hears the voices of those customers only whom he had overcharged, complaining that he makes them pay more than others for the same articles. Lastly, he hears the voices of those customers only who have telephones installed in their houses, and none of the others. These psychological observations are not only interesting but important, and anyone who ignores them and fixes his attention on alcoholic poisoning alone is pursuing an unscientific course, even though the psychologist does not cover the whole ground. Were the mental suggestion of the possession of a telephone and the sensitive soil of the guilt-stricken mind not essential elements in these hallucinations? The hallucinations did not occur when the patient made out the accounts of those customers who did not possess telephones.

We know, further, from clinical experience that psychic factors of a special kind, if sufficiently powerful, may produce mental disorder in a person with a sensitive mind, not necessarily abnormal or diseased, which psychic therapy is able to remove. Thus had the licensed grocer inherited this mental disposition, the threat of exposure, disgrace, and ruin might have produced the same hallucinations as he suffered from, without the aid of alcohol. So, also, a girl may react to a disappointment in love by an hysterical symptom or a fantasy, and she can be cured of her faulty adaptation to the needs of her environment by psychic means. And in still more serious mental disorders the psychic element plays its part,

but in these the foundation of the disorder may be sunk so deeply in the hidden recesses of the mind that only psycho-analysis, of all the known methods at our disposal, can reveal it.

Let all beware of adopting to psycho-analysis the attitude of Thomas Carlyle to evolution, who dismissed that doctrine as false because its views were intolerable to him. But, he admitted, he could never read a page of the stuff! It is necessary not only to read and understand the doctrine of psycho-analysis, but also to put it personally to the test of clinical experience before expressing decided views about it.—I am, etc.,

University of Edinburgh,  
Dec. 25th, 1922.

GEORGE M. ROBERTSON.

SIR,—In your issue of December 23rd, 1922, one of your correspondents seems to think that it is a sufficient answer to the questions raised—that “psycho-analysis works.” I don’t think anyone has denied that in a certain number of cases a cure is brought about after psycho-analysis, but so it is in probably a larger number of minor mental cases by talking over matters and reasoning with the patient—the method that has been used by many doctors for a long time. That is psychotherapy, but it need not be the Freudian method of psycho-analysis. Faith healing, Christian Science, and visits to Lourdes may also “work” in some cases, probably chiefly by suggestion, but that is no reason why they should find their place as a recognized form of medical treatment. Physiologists freely admit the importance of inherited physical and physiological cerebral associations, and dynamic associations, the result of experience, or of the reaction of the organism to its environment in the building up of the mental life of an individual, and the method of free associations may have a limited place in the investigation and diagnosis of a certain number of cases, but this is a small part of Freudian psycho-analysis.

One of your correspondents states that they do not deny the physiological basis of thought. Perhaps many don’t, but more is required than that. Do physiologists accept the many conclusions on which psycho-analysis is based? Do physiologists admit Freud’s theory and interpretation of dreams, the *via regia* to psycho-analysis? Are their views not more in accord with those shortly stated by Professor Berry? Are Freud’s views as to a censor between the unconscious and the conscious mind accepted by physiologists? Is it a reasonable hypothesis, far less being in accordance with what physiology teaches, to suppose that in each of us there is a censor, nominally on a lower level than consciousness, endowed with ideas, knowledge, ingenuity, and imagination which make the plots of a Conan Doyle and his creation Sherlock Holmes pale into nothingness?

This censor is supposed to have more knowledge than the conscious ego, and to act by keeping some of that knowledge from and practically deceiving the conscious ego, not only in dreams, but in certain mental states. Can anyone imagine anything having knowledge and yet not being conscious? Yet this censor, by means of symbols, etc., of which it seems to have at its disposal an enormous vocabulary, transforms the information it possesses; works out elaborate plots in order to do—what? To deceive the consciousness! In dreams the censor transforms the “latent” content of the dream into the “manifest” content. In doing so it may reverse it, use one thing for another, one symbol for another, do almost any thing with it. The “manifest” is what the dreamer dreams; the “latent” is what the interpreter imagines it was before it was censored. Physiologists have, of course, long recognized the importance of inhibition in all nervous processes, but the Freudian censor goes far beyond that.

Another correspondent disapproves of Professor Berry quoting from what he calls “popular drivel.” The fact that psychology is too often divorced from physiology accounts for so much drivel being published. Much of it might be a contribution to speculative philosophy; it should have no place in serious medical literature.

Let us by all means as a scientific profession encourage scientific psychotherapy, psychiatry, and experimental psychology, but let us recognize the limitations of psycho-analysis and get rid of its extravagances.—I am, etc.,

WILLIAM ELDER, M.D., F.R.C.P.E.

## THE PYREXIA OF HODGKIN’S DISEASE.

SIR,—The publication (December 23rd, 1922, p. 1201) of the admirable post-graduate lecture on Hodgkin’s disease by the late Sir James Galloway emphasizes the great loss which clinical medicine has sustained by his untimely death. I am particularly interested in the case there recorded because he told me about it and of his intention of recording it, when we met at the annual meeting of the Association of Physicians at Oxford last April, where the subject of recurring pyrexia in these conditions was discussed.

It is very desirable that such cases should be recorded, for there is no doubt that in all there must be some common factor causing this remarkable form of rhythmic temperature curve.

In the paper recently published in the *Quarterly Journal of Medicine*, referred to in Galloway’s lecture, Professor Douglas and I showed that of the cases already published the “pyrexial span”—that is, the time between corresponding periods of successive waves of fever—was in 86.5 per cent. of the cases between fifteen and twenty-five days. Galloway’s case comes also within these limits. The first three “pyrexial spans” are about twenty days each. In the pyrexial period in late December something has interrupted its decline, and although there has been an attempt to return to normal it is overcome by a second ascension. The recurring periods after this also show a distinct regularity, but the “stride” or “span” is shorter—namely, about sixteen days.

This change of span during the course of a case is by no means uncommon. It is well seen in a case recorded by the late Sir Frederick Taylor (Case No. 2, *Guy’s Hospital Reports*, 1906), where the span changes from about twenty days during the earlier part of the chart to about sixteen days in the later. In Melland’s (*Edinburgh Medical Journal*, 1911) case also the spans varied between sixteen and twenty days. A similar change was present also in a chart (unpublished) recently shown me by Professor Russell of Birmingham. In his case there was, as in this, an interruption to the expected decline of one pyrexial period, which marked the change in “span” from longer to shorter.

Galloway’s chart shows all the characteristics: the sub-normal temperatures during apyrexial intervals; the steppage upwards, to which MacNalty called attention, which begins before the temperature gets above the normal level; and the constancy in height of successive peaks. Of the eight peaks recorded, the extreme height only varies between 103.8° and 104.8°; if we omit the first recorded, which only shows the beginning of the decline, and was probably higher at its peak, the remainder show only a difference of six-tenths of a degree, 104.2° to 104.8°.

This constancy of height in any particular case is one of the most remarkable features in these temperatures. In one case it may be always 105° or even higher, in another only 102° or 103°. Whatever it is, it usually repeats itself with surprising constancy. When one considers that these temperatures are often, as in Galloway’s case, passing through 10° Fahrenheit in the course of a few days, this is a somewhat remarkable fact.

As regards measurement of “pyrexial span,” it seems preferable to measure from the middle of one “pyrexial period” to the middle of another. Sometimes the actual crossing of the “normal line” occurs a little sooner or a little later in successive curves, so that measured from the actual point of such crossing to a similar point at the next rise, there may be an appearance of irregularity in what are obviously very regular waves. It must be remembered that we are here dealing with the waves as a whole. Although the exact date of this patient’s death is not recorded, yet from internal evidence it seems to coincide with the end of the chart, and the appearance of the “pre-lethal” span with the rise of temperature just before death corresponds with others to which attention was called in our paper.

The form of “standardized chart” Galloway used in this case is a considerable help in making these cases more clear. By presenting the temperature curve in this form it is possible to see it as a whole and realize its symmetry in a way which the proportions of an ordinary temperature chart make impossible. The symmetry becomes even more clear if horizontal and vertical lines are used, as was suggested in our paper, in place of the “dot and slope” of the ordinary chart.

Finally, the question why the temperature behaves in this unusual way in these cases of Hodgkin’s disease remains unanswered. Various writers have from time to time

suggested the possibility of a parasitic origin, and attempts have been made, hitherto without success, to discover such a parasite. Douglas and I, in the paper referred to by Galloway, detailed our reasons for thinking a parasite probable, and the knowledge that so able and experienced a clinician as the late Sir James Galloway inclined to the same view strengthens us in our opinion.

The fact that no parasite has yet been found is not conclusive evidence against its existence. These cases are not very common, so that opportunities for investigation are not frequent, and it must not be forgotten that even in a very common disease where opportunities were constantly present—namely, malarial fever—it was a considerable time before the parasite was discovered.—I am, etc.,  
Sheffield, Dec. 23rd.

ARTHUR J. HALL.

#### ADDER BITE.

SIR,—The perusal of Sir Thomas Oliver's interesting article on adder bite impels me to translate for the benefit of your readers the following graphic description from the pen of Dr. Bernard, erstwhile of Cannes<sup>1</sup>:

"On arriving at the caravansary of Bou Ghzoul, about half-way from Algiers to Laghouat, I found the bedouins crowding round the entrance, a prey to violent excitement. They had just killed a horned viper, one of the most dangerous varieties of the viper family. It was nearly four feet in length, and though dead its tiny eyes glittered like jet. The skin was of a light grey colour with black patches. The body, short and thick, was nipped at the end and finished off in a sort of rat's tail, hideous to behold. The head, flat, square, indented, was surmounted by two little curved horns about half an inch long. The mouth looked small, but when the animal prepares to bite it gapes horribly, like the mouth of a giant toad. Some of these animals attain six feet in length, the body being as thick as the wrist and the head the size of a child's fist.

"On inquiry I found that the reptile had, six hours before, bitten a native, and the people were the more astonished thereat, seeing that the victim enjoyed a great reputation as a serpent charmer. It appeared that he was cutting alfalfa grass to light the fire, watching the *lefau* (native name for vipers) as they rushed hissing away, climbing up the rocks to a cave which was known to be full of them. This particular viper was probably asleep and the man had grasped it unawares in taking hold of a bundle of grass. The serpent thereupon had bitten three fingers of his left hand. Greatly scared, he had tied his turban cord tightly round the arm and started running to the caravansary. This was only ten minutes distant, but by the time he reached there his arm up to the ligature had swollen enormously. The *toubib* (native medicine man) had deeply incised the flesh with a small knife used by them as a razor and stuffed the wound with a chopped-up plant that stings like a nettle. After the operation he pronounced certain cabalistic formulae in a language not understandable by any human being. The patient meanwhile said never a word, but bore the pain with absolute stoicism.

"At this juncture there was a movement in the crowd, for the victim, as it happened, belonged to a neighbouring tribe, and his relatives had rushed over to take charge of him. He passed before me, half reclining in their arms, wrapped in his blood-stained bournous, looking very sick of the whole business. As the procession wended its way out of the caravansary the *toubib* shouted to them a final piece of advice—namely, that if the man became feverish they should 'trample on his belly,' which would squeeze out the fever as it would the juice out of the grape.

"He will die all the same, remarked an alfa reaper, who seemed to take a good deal of interest in the accident. He will die because, when all's said and done, there is only one real remedy, and that is to chop the fingers off. Look, said he, and he showed me his left hand which lacked the second and third fingers. I was bitten once upon a time but fortunately I had a chopper in my hand and I cut off the two fingers right away, and here I am to tell the tale. So you see!

"But suddenly we hear cries of despair, ghoulishly lugubrious; heard in the darkness of the night they make one's flesh creep. They emanate from the women, who are bringing back to the caravansary the man who had been bitten by the viper. Fantastically lighted by burning branches the white procession stood out against the dark rocks, and again I caught sight of the Arab, still whispering that he is swelling up, ached the chest, and they have treatment that the *toubib* alone can

apply. . . .

"I prepared to mount my fiery Arab steed next morning when it occurred to me to inquire about the man's history. How about the Arab bitten by the *lefau*, I asked of my spahi? Oh, the Arab, oh, he's all right, he's dead. You can see him if you like, he is swollen up to the size of a barrel."

Only the other day the native gardener on a neighbouring property came to me to be treated for a scorpion sting. On removing the summary dressing I was startled to see a young scorpion flattened out on the site of the sting. What's that? I asked. Oh, said the man, we always do that. We are told

that there is no better remedy than to apply the crushed animal to the wound. The sting had been inflicted a quarter of an hour earlier, and so far there were no symptoms, local or constitutional. I injected a few drops of a strong solution of potassium permanganate round about the spot and nothing happened. It may be that as it was only a baby scorpion it had not yet become virulent. While not usually fatal, the results of the sting of an adult scorpion are usually very severe, though this depends greatly upon the time of year and possibly, too, on the particular variety of scorpion. Though plenty of scorpions are to be found in the neighbourhood of Algiers it is an extremely rare event for anybody to be stung as far as my experience goes.—I am, etc.,

Algiers, Dec. 22nd.

ALFRED S. GUBB, M.D.

#### HOSPITAL POLICY.

SIR,—The revived discussion on hospital policy is happily confined to a very clear and simple issue. The Council in its further Report (SUPPLEMENT, November 18th, 1922) reaffirms the principle that all payments made by, or on behalf of, patients must suffer a compulsory contribution to the medical staff fund. The words now suggested differ, it is true, from those of the paragraph rejected at Glasgow, but there is no change in the meaning and intent. The new proposal can therefore hardly be expected to satisfy the views of those who have on repeated occasions contended that it is not in accordance with the traditions of the medical profession or of honorary hospital service to accept payments, even token payments, from patients who are unable to do more than make some contribution to the expenses of their accommodation and maintenance. Such being the position it remains for the Divisions (and in due time for the Representative Body) to come to a decision on the issue thus joined. What falls immediately on those of us who unhappily differ from the Council's proposal is to find a form of words that can be moved as an amendment to the Report. Some attempts have already been made in this direction, but these, at least so it seems to me, fail to put in the forefront the positive aspect of a policy which has as its essential feature the continuation of honorary medical service to necessitous patients. With due respect, therefore, I suggest that the Divisions, when discussing the Council's Report, should consider the possibility of an amendment on some such lines as the following:

"That (excluding the question of payments made by private patients referred to in Sections IX (a) and IX (b)) the medical staffs of hospitals should retain their honorary status by continuing to provide gratuitous advice and treatment for all patients found on due inquiry to be unable to pay more than the sum estimated as sufficient to meet the charges for their accommodation and maintenance, but that in any case where the payment accepted is in excess of this sum, as also in the event of an arrangement being made for the treatment of patients on behalf of the State, municipality, or other public body, or under a hospital benefit or insurance scheme or any similar organization, a percentage of the amounts received by the hospital must be passed to a fund to be placed at the disposal of the honorary medical staff of the hospital."

The Council's policy is that every patient must needs contribute something to the hospital doctors' fund. The amendment here suggested opposes this innovation, continues the hospital tradition, and at the same time provides safeguards against the exploitation of the medical profession. My present purpose is not to repeat arguments about which most of us have already made up our minds, but rather to sketch a plan of campaign for those who, on the point in question, cannot accept the policy advanced by a majority of the Council.—I am, etc.,

London, W., Jan. 1st.

C. O. HAWTHORNE.

SIR,—The new hospital policy of the Council is the Leicester policy thinly disguised, and as the latter is so patently inapplicable generally that it has never been promoted anywhere where almoners are allowed, the former is scarcely more acceptable to the profession or the public. I would suggest the following compromise, devised after attending three London meetings of hospital representatives, at one of which both lay and medical staffs were heard, after correspondence with exponents of the most opposite views, and, last but not least, after two consultations with our hospital lay board, who are capable, friendly, and successful in hospital finance.

These proposals distinctly transgress that limit of safety set by the Cave Committee, and may be rejected on that account by some staffs and many lay boards, who are

<sup>1</sup> L'Algérie qui s'en Va. Librairie Plon. Paris.

likely to attach greater importance to an authority which patiently heard lay and medical experts than to any one-sided opinion. They would bring about, if accepted, a grave departure from the policy which was universal up till 1921, was approved by Scottish staffs in that year, and is still very generally popular and in operation. Therefore they mark, in my opinion, the extreme limit of possible concession to that revolutionary party who have lately beguiled the Council. These men have in two years conceded practically nothing, declining to consider any areas but their own. They are, I believe, far less numerous than one would gather from meetings, for it is notorious that the man who is content is apt to stop away. Any further yielding to them spells ruin to the voluntary system, since it is allowed that, under the new scheme, lay boards must also be paid, and no one has even hinted whence, under any voluntary system, such funds shall be raised. Also it would inevitably bring us into violent and disastrous conflict with lay opinion, in which we should certainly be the losers, and probably sacrifice what we have already won.

#### AMENDMENTS TO SECTION VI, PARAGRAPH 19 (SLIGHTLY MODIFIED SINCE THE GLASGOW MEETING).

(a) *Ordinary Hospital Patients* (receiving free treatment from the medical staff).—Those who can produce evidence satisfactory to an official of the hospital that they are unable to contribute anything towards their cost while in hospital, or, at any rate, not more than such sum as may be agreed upon between the medical staff and the lay board as representing the expenditure on their mere maintenance and accommodation, as distinct from treatment, and who do not come within the definition of "tariff patients."

(b) *"Tariff Patients."*—1. Those for whom is paid in part or in whole the tariff cost of maintenance or treatment by public authorities, approved societies, employers of labour, insurance companies, or other bodies.

2. Those for whom the above payment is made under any contributory scheme which involves definite financial arrangement between the Board of Management and the contributors, or which carries any claim to admission in priority to the "ordinary hospital patients" in class (a).

3. Those who are deemed able, personally or through their responsible relatives or guardians, to contribute a weekly sum in excess of that required for accommodation and maintenance only, who are therefore ineligible as "ordinary hospital patients" under class (a), yet have not means necessary to qualify as "private patients" under class (c).

In conclusion I would quote the Cave Committee:

"The voluntary hospital system, which is peculiar to the English-speaking peoples, is part of the heritage of our generation; and it would be lamentable if by our apathy or folly it were suffered to fall into ruin."

Dr. Fothergill's letter, which I have just read, is a most useful contribution to the controversy. It will be seen that some such modification of Section VI, paragraph 19, as I suggest would follow necessarily on the acceptance of his resolution. I am not quite clear whether we agree as regards mass contributions. Public opinion would not tolerate the exclusion of the genuinely poor from Class A merely because they have paid a penny a week to a village fund, and expect nothing in return.—I am, etc.,

Chichester, Dec. 30, 1922.

G. C. GARRATT.

#### PSYCHIATRIC CLINICS.

SIR,—I write in reference to Dr. R. H. Steen's letter of November 18th, Dr. H. E. Davison's of December 16th, and Dr. Laughton Scott's of December 30th, 1922. Dr. Steen makes an admirable statement of the necessity of establishing psychotherapeutic clinics; Dr. Davison enlarges upon this necessity, and finds the only obstacle in the apparent shyness of the "open-handed philanthropist"; and Dr. Laughton Scott suggests that the financial difficulty is not really serious. The experience gained at the Tavistock Clinic is, I think, sufficiently relevant to the discussion to justify me in quoting it. The clinic treats an average of 350 cases a year. In round figures the revenue and expenditure are as follows:

Revenue.		£	s.	d.	Expenditure.		£	s.	d.
Patients' fees	...	403	0	0	Doctors' and lecturers' fees	...	1,200	0	0
Lecture fees	...	500	0	0	Running expenses	...	450	0	0
Public subscriptions and donations	...	750	0	0					
		£1,650	0	0			£1,650	0	0

It will be seen from these figures that without the aid of "the open-handed philanthropist," and indeed with relatively little support from the public, the clinic is able to remain solvent. It will also be seen that three-quarters of the

revenue is spent upon payments to the medical staff. This apparently is not contemplated by Dr. Laughton Scott; but on the other hand it is an entirely different proposition from Dr. Steen's, for he refers to "whole-time, well-paid, and comparatively numerous medical officers." While I accept the principle of payment to the medical officers, I believe that in general they should be part-timers, for the reason that serious psychotherapeutic work is too exacting for the average man to carry on continuously under the same conditions and in the same environment with advantage.

Dr. Steen raises the question of the time that should be available for each patient. At the Tavistock Clinic we have from the beginning worked on the principle that every patient should have as much time devoted to him as appeared profitable, without reference to the demands of the waiting list. In treating an average of 350 patients a year the average number of attendances by a patient worked out at nine; but this figure is misleadingly low on account of the fact that a large number of cases are only seen once and not considered suitable for a regular course of treatment. The average duration of a patient's interview is fifty minutes.

But the real crux of this work lies not in the financial difficulty, nor in the "conversion of the medical profession" (the Tavistock Clinic has always had as many patients as it could cope with, and the large majority are recommended by their doctors): it lies rather in the personal factor. With the heavy crop of aspiring students of psychotherapy there is a serious dearth of qualified and effective psychotherapists. Dr. Steen's band of enthusiastic students forms the right kind of nucleus for a beginning; but it is useless to hope that enthusiasm and a little experience will make up an effective psychotherapist. It is even useless to count upon results because the psychotherapist has had great experience and has been analysed *à outrance*. These are valuable qualifications, but in the absence of certain essential innate characteristics they are not sufficient to make a good psychotherapist; and it is only the good psychotherapist whose results will maintain a respectable level. I believe that those who have had the greatest experience of students of psychotherapy—Dr. H. E. Davison or Dr. Bernard Hart, who under Dr. Rowse had more to do with the making of psychotherapists at Maghull than anyone else—would endorse this opinion.

It is my conviction that if the cause of modern psychotherapy is to be maintained, and the public well served, clinics should be established only in so far as really competent psychotherapists can be supplied. Otherwise clinics will be established with vacant posts to act as a temptation to the men who are tired of general practice; who have an infatuation for the *dernier cri*; who imagine that psychotherapy is a path to effortless success; or who are otherwise unqualified for the work that is to be undertaken.—I am, etc.,

London, W.C.1, Jan. 1st.

H. CRICHTON MILLER.

#### THE TEACHING OF PSYCHOTHERAPY.

SIR,—As my letter to you was the humble means of starting this interesting correspondence, perhaps you will allow me space for comment thereon. Nothing could better prove the existence of the unconscious mind than the naïveté of the opposition, as shown by some of the contributors.

The letters of Dr. Berry and Dr. McBride published in your issue of December 9th are striking examples of the influence of the emotions in paralysing the accommodation of scientific thinkers, thus rendering them blind to the meaning of words and sentences which they would readily understand were they used in any other connexion. Dr. Berry quotes two perfectly intelligible sentences from two psychological works, and frankly admits that to him they appear to be unintelligent rubbish; whilst Dr. McBride takes two paragraphs from Dr. Steen's letters and is apparently unable to see the difference between their obvious meaning and the interpretation which he prefers to place on them. As both these gentlemen are clearly acting in good faith it is impossible to explain this kind of aphasia on any other ground than that of the internal resistances aroused by the threat to the unconscious of laying bare its content.

In his *Introductory Lectures on Psycho-analysis* Professor Freud takes full account of this instinctive defence mechanism on the part of those who are commencing the study, and by leading his readers on gently, step by step, enables them to overcome their own inhibitions. His lucid style will come as a pleasant surprise to those who only know him through the medium of his commentators, and I recommend those who

can see nothing but rubbish in his theories to read and reread this book, and then to test the theories on themselves and others before again airing their views.

The ultimate test of all theory must be that of its practical working, and in the case of Freud such tests can only result in conviction. Dr. Berry will find that Freud by no means ignores the effect on the dreamer of enteroceptive and exteroceptive impulses, but whilst these may partly account for the outlines of the dream they cannot account for the pattern formed. Why suppose that these impulses run riot and refuse to search for any possible laws which may control them?

I have no quarrel with Dr. Berry's contention that the psychological physician should be a sound physiologist and neurologist; but both he and Dr. McBride should realize that physiology and psychology deal with two entirely different aspects of life, and that each must necessarily have its own terminology. That physiological activities accompany psychic processes and vice versa is undeniable, but the exact working of this partnership is at present a matter of speculation.—I am, etc.,

Wylde Green, Birmingham,  
Dec. 10th, 1922.

R. MACDONALD LADELL.

#### DIPHTHERIA PROPHYLACTIC AND IMMUNITY.

SIR,—The question raised in Dr. H. Cooper's letter in your issue of December 23rd, 1922 (p. 1244), is one of some importance. A group of workers at this laboratory has been investigating cases similar to the one described, and we hope to publish our results in the near future. We may here anticipate our results by stating that we have as yet found no evidence that indisputable diphtheria—that is, serious illness caused by intoxication arising from *B. diphtheriae*—ever occurs in a patient who has given a "negative" response to a satisfactory Schick test.

We may also point out that the 95 per cent. conversion of a "Schick positive" population to a "Schick negative" one occurs only when dealing with children; in an adult population, consisting of "Schick positive reactors," the rapidity and efficiency of immunization is much less.

We wish to obtain material from cases such as that described by Dr. Cooper, or from those where there is clinical justification for suspecting diphtheria in a patient who has previously given an undeniable Schick negative reaction. The three essentials are: a swab from the patient, 5 c.cm. (or preferably 10 c.cm.) of blood taken from the patient's vein immediately before any antitoxin is given, and another 5 or 10 c.cm. taken seven or ten days later.

We would gladly examine these materials and send the results to the physician concerned.—I am, etc.,

R. A. O'BRIEN.

Wellcome Physiological Research Laboratories,  
Langley Court, Beckenham, Kent, Jan. 1st.

#### TREATMENT OF FRACTURES BY OPERATIVE METHODS.

SIR,—Professor Young's interesting paper (December 23rd, 1922, p. 1209) on the operative treatment of fractures raises again the important question of the best material to use in these cases. I am glad to see that he has discarded silver wire and screws in favour of iron nails and screws, but I am surprised at his using brass wire when he has in pure malleable iron (not steel) a stronger, more flexible, and more reliable material, one not influenced by any heating for sterilization and not acted on by any of the tissues, while brass is corroded by animal fats. The plates also should be light and made of the same material; most of those in use are unnecessarily thick and heavy.

Professor Young does not mention what drills he uses for the hard bones. I have found that the Morse twist drill, as used by engineers, is far superior to the spud drill usually supplied to surgeons; and in my experience there is nothing so reliable, both for putting in and removal, as ordinary carpenter's screws, which can easily be obtained in every variety of length and size.

I cannot quite agree with Mr. Hey Groves that a screw for dense bone should be of the engineer's variety, but I think that Lane's screws, which are threaded up to the head, leave nothing to be desired for thin plates. Everything depends, of course, on the accurate relation of the hole to the screw.—I am, etc.,

CHARLES FIRTH, M.D.Lond., F.R.C.S.Eng.,  
Consulting Surgeon to the Gravesend Hospital.  
Gravesend, Dec. 27th, 1922.

#### SMALL-POX AND VACCINATION.

SIR,—Dr. Millard now admits that cases of small-pox may walk about for a time. There is little to add to the discussion. I fear that no matter what I say, Dr. Millard will say I am "begging the question."

In thanking you for the courtesy of your columns, might I say that if anyone wishes to procure a really fine article on how to suppress a small-pox outbreak, let him write and ask Dr. Alexander, medical officer of health of Poplar, for a copy, similar to that sent to metropolitan medical officers of health, of his report on the Poplar outbreak.<sup>1</sup> Dr. Wanklyn's books, of course, are classics.—I am, etc.,

CHARLES S. THOMSON,  
Medical Officer of Health.

Town Hall, Deptford, S.E.14,  
Dec. 27th, 1922.

#### TREATMENT OF MALTA FEVER.

SIR,—Admiral Sir P. W. Bassett Smith's article on undulant (Malta) fever in the JOURNAL for November 11th is very instructive, and the mention of the relationship between infectious abortion in cattle and Malta fever is specially valuable. A good deal of investigation into this point is now being done in Rhodesia. But under the heading of treatment nothing is said as to the effect of the arsenical preparations—606, galy, kharsivan, novarsenobillon, etc.

A few years ago I reported in the *South African Medical Record* some cases in which very striking results had been obtained by the use of galy intravenously or preferably intramuscularly, and I believe an abstract of this paper appeared in the JOURNAL. Being away from home and my papers I cannot give the exact dates. I hoped this report would attract the attention of those who see more Malta fever than I do, and have better opportunities for studying the effect of treatment. My most successful case was one in which the patient, a man of about 35, living under the most favourable circumstances, had suffered from repeated severe attacks (temperature often 104°) for several years, and had gained no benefit from a long course of autogenous vaccine, yet he was absolutely cured by one intravenous injection of galy. As this was five years ago and there has been no recurrence I think "absolutely cured" is correct.

I notice that Sir P. Bassett-Smith's own approval of vaccine treatment is rather guarded.—I am, etc.,

E. OLIVER ASHE, M.D.Lond., F.R.C.S.Eng.,  
Senior Surgeon, Kimberley Hospital, South Africa.

Johannesburg, Dec. 10th, 1922.

#### Obituary.

J. J. PRINGLE, M.B.EDIN., F.R.C.P.LOND.,

Consulting Physician for Diseases of the Skin, Middlesex Hospital.

WE regret to announce the death of Dr. J. J. Pringle, the well-known dermatologist, on December 18th, 1922, at Christchurch, New Zealand. Recently on retiring from practice he hoped to find renewed health in a voyage taken to Australia and New Zealand. From the latter place the news of his death has been received.

John James Pringle came of a Scottish family which numbered among its members the celebrated Sir John Pringle. He received his early education at Merchiston and at Edinburgh University, where he graduated M.B., C.M. in 1876. After holding the appointment of resident physician at the old Royal Infirmary he spent four years in further study in Vienna and Paris, and it is probable that this period had a considerable influence upon his future career, for he came there under the influence and teaching of four masters of dermatology—Hebra, Kaposi, Vidal, and Fournier. While to this period may be traced the beginning of the interest in the special branch of medicine he practised, his earlier professional years were not occupied with dermatology but with general medicine.

Coming to London in 1882, he was elected to the post of medical registrar at Middlesex Hospital in 1883, then assistant physician—an appointment he held for ten years—and finally physician to the Department for Diseases of the Skin in succession to Dr. Liveing. To the wider experience gained as an assistant physician he attached much importance, and in his gift of recognizing the larger factor in cutaneous disease he often gave convincing proof of the value of his early training. But it was as a dermatologist that he was known in

<sup>1</sup> This report was referred to briefly in the BRITISH MEDICAL JOURNAL of December 23rd, 1922 (p. 123).

this country and abroad. He devoted himself with enthusiasm to his chosen subject, both in its practical part and in what may be termed the academic side. He had a distinct literary gift, and his contributions are models of correct style and lucid exposition. This gift he put to good purpose as editor of the *British Journal of Dermatology*, a post he held for many years. He was for sixteen years secretary to the old Dermatological Society of London.

Dr. Pringle was an accomplished linguist, speaking and writing both German and French fluently. This brought him into close association with his foreign colleagues, and was no doubt one of the reasons which caused him to be chosen Secretary-General to the International Congress of Dermatologists in 1895. In 1913 he became President of the Dermatological Section of the Royal Society of Medicine, and here his genius for organization found opportunity in many reforms and improvements of procedure. His foreign colleagues also honoured him by conferring upon him the corresponding membership of the French, Vienna, Berlin, Italian, and Lisbon Dermatological Societies. He was the author of many papers, and to one particular condition first described by him the name "Pringle's disease" is often attached by dermatologists. Although no book appears from his pen alone, he may be said to have largely inspired the well-known work to which his name and Jacobi's are attached.

Although his private practice was large he never allowed any outside engagement to interfere with hospital duties. These he carried out with unfailing regularity: his clinical assistants knew he would be present at the appointed hour, that he would give the same care and attention to the last patient as to the first, and that even after a long and tiring day in the out-patient department his work would be completed with the thoroughness which was characteristic of the man. As a teacher he attracted many followers and he spared no pains to instil the elements of dermatology into the junior students. Perhaps he was even more successful with senior workers, who found in him an inspiring example. Of his former clinical assistants, six are dermatologists in London hospitals. During the war the department of which he had charge suffered from the conditions then obtaining. Pringle willingly undertook the additional work thus created and he further organized a department for diseases of the skin at No. 3 London General Hospital, carrying it on with success from 1914 to 1919. It will be remembered that during the later stages of the war period the authorities launched their scheme for the treatment of venereal diseases. For the success of this scheme he worked with enthusiasm, organizing at Middlesex Hospital the special department upon lines which have fully justified his foresight and judgement.

For many years Dr. Pringle's health had been indifferent, and when the additional strain of his war work came he must often have been tempted to curtail his public duties. But these he regarded as a task to be carried on regardless of personal discomfort so long as they might be required. If he received no or little recognition he sought none, content to feel that he was forwarding the cause he had at heart. Pringle's place is undoubtedly among the great British dermatologists. He was always a leader of progress, careful to listen to new ideas, constantly improving and advancing. He was an enthusiastic musician, and found in music his chief recreation. Those who knew him well were aware how seriously he was handicapped by ill health, and saw and admired his courage. He was a loyal friend, and there must be many who have cause to remember some kindly act on his part.

#### HARRY POOLE BERRY, O.B.E., M.B.,

Chairman of the Kesteven Division, British Medical Association.

WE regret to announce the death of Dr. H. Poole Berry, which took place at Grantham on December 19th, 1922, at the age of 63, after a short illness. He graduated M.B. Lond. in 1883 from Guy's Hospital, where he held resident appointments, and started practice at Grantham thirty-seven years ago. He was for many years M.O.H. to the urban district, and had a long association with the Grantham Hospital, of which he was senior surgeon at the time of his death. He was also then occupying the position of Chairman of the Kesteven Division of the British Medical Association. Dr. Berry had a very large connexion with the 2nd Volunteer Battalion, and afterwards, when the Territorial scheme was formed, with the 4th Battalion of the Lincolnshire Regiment. He obtained his captaincy in 1890, and became surgeon-

major in 1902. The regiment was mobilized in 1914, and he served for a considerable time both at home and in France. He was invalided home in 1915, and it was a matter of regret to his friends that he never recovered the juvenile appearance and activity which had been so marked before the war. Nevertheless, he subsequently did very valuable work in connexion with the Red Cross Hospital at Grantham, and no one more deserved the O.B.E. which was bestowed on him. Other honours included the Territorial Decoration and the Volunteer Long Service Medal. He was always a hard worker, and his professional skill, sincerity, and kindly disposition were valued alike by his colleagues and his patients. A striking tribute was paid to his memory by the large attendance of people at the funeral on December 23rd. He leaves a widow and a married daughter, who have the heartfelt sympathy of his many friends.

Dr. CORNELIUS BIDDLE died at Merthyr Tydfil on December 16th, 1922, after a long illness. He was born in 1848, and received his medical education at Charing Cross Hospital, taking the diplomas of M.R.C.S. Eng. in 1870 and L.R.C.P. Lond. in 1871. Returning home, he built up an extensive practice in Merthyr Tydfil, where for forty years he held the esteem and confidence of his fellow townsmen. He was one of the four surgeons to the Merthyr General Hospital since its foundation, and brought to his patients the skill and resource that a large industrial area demands. He found time to interest himself in public work, and his dignified presence and graceful speech won him the highest honour in the gift of his fellow townsmen, for he was chosen the last High Constable of Merthyr. For many years he was a justice of the peace of the borough. He was keenly interested in matters medical, and was treasurer and a former President of the South Wales and Monmouthshire Branch of the British Medical Association; he set a high value on membership of the Association and never missed an opportunity of urging its value on his younger colleagues. Although he was close on 70 years of age and had retired from practice when the war came, he took upon himself the work of his colleagues on active service, bringing to it a vigour and freshness that excited astonishment and admiration. He also held a commission in the local Volunteer Defence Corps, attended all its meetings, and carried out its training. He leaves a widow, four daughters, and two sons who are both members of the medical profession.

Dr. ERNEST VICTOR GOSTLING, of Needham Market, Suffolk, died at Felixstowe on December 30th, 1922, aged 50. He was educated at Framlingham College, at Caius College, Cambridge, and at St. Thomas's Hospital; he graduated B.A. Cantab. in 1896, and took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond. in 1900. After qualifying he held resident posts at Addenbrooke's Hospital, Cambridge, and at Derby Royal Infirmary. At Cambridge he had captained his college cricket club and represented the university at association football. He was greatly interested in the Territorial Army, and held the rank of lieutenant colonel in the R.A.M.C. (T.). He formerly commanded the East Anglia Field Ambulance, with which he proceeded overseas on the outbreak of war, and was at the first landing at Suvla Bay. He was slightly wounded, and gained the D.S.O. Subsequently he held the post of A.D.M.S. in England until he was demobilized in 1919.

Major WILLIAM HENRY HENDER BENNETT, R.A.M.C. (T.F.), died at Batley, Yorks, on December 9th, 1922, aged 61. He was educated at the Universities of Sydney and Edinburgh, graduating at the latter as M.B. and C.M. in 1890. After serving as clinical assistant in the eye wards of Edinburgh Infirmary and as assistant medical superintendent of the Argyll and Bute Asylum, he went into practice at Batley, where he was honorary surgeon to the Batley and District Hospital. He took a commission as lieutenant, R.A.M.C. (T.F.), in the 4th (Wakefield) Territorial Battalion of the King's Own Yorkshire Light Infantry on October 30th, 1914, became captain on April 30th, 1915, and was afterwards promoted to major.

Dr. IWAN BLOCH, a writer on sexual disorders, has recently died in Berlin at the age of 50.

## Universities and Colleges.

## UNIVERSITY OF ST. ANDREWS.

THE following candidates have been approved at the examinations indicated:

**THIRD M.B., Ch.B.—Forensic Medicine:** F. El Ahmadi, C. B. Armit, T. F. Black, R. Blair, W. R. C. Campbell, R. H. Craig, W. Cunningham, J. W. A. Dennis, T. A. Doran, L. Farrell, D. R. Ferens, H. J. Fraser, C. H. S. Gowdie, J. S. Gururwar, J. A. G. Keddle, L. R. Khan, J. M. A. Lowson, A. K. McCowan, J. C. MacMillan, D. F. Menzies, J. R. Murray, D. Myles, G. Napier, D. M. Ross, B. W. Rycroft, J. D. Saggart, A. Shand, J. D. Sinclair, D. Stewart, C. F. Swinton, J. Wilson. **Public Health:** F. El Ahmadi, C. B. Armit, T. F. Black, R. Blair, W. R. C. Campbell, R. H. Craig, W. Cunningham, J. W. A. Dennis, T. A. Doran, L. Farrell, D. R. Ferens, H. J. Fraser, C. H. S. Gowdie, J. M. A. Lowson, A. K. McCowan, J. C. MacMillan, D. F. Menzies, D. Myles, G. Napier, J. Petrie, D. M. Ross, B. W. Rycroft, J. D. Saggart, A. Shand, J. D. Sinclair, R. P. Sood, D. Stewart, C. F. Swinton, J. Wilson.

**FOURTH M.B., Ch.B.—Medicine:** J. Craigie, Jean M. Davidson, H. Fisher, P. G. Grant, S. S. Ogilvie, J. E. Overstad, Nora A. M. Rodger, Blanche D. S. Spence, W. A. Steel, A. K. Tateston, W. Thomson, T. Wilson. **Surgery:** W. S. D. Elder, Ruby N. Foggie, P. G. Grant, O. R. Henderson, Mary M. Jack, Nora M. Lindberg, Gracie M. McRorie, Jean H. Morton, Janet L. A. Muirhead, S. S. Ogilvie, A. B. Richardson, Nora A. M. Rodger, J. Singh, Janet O. Stephen, W. Thomson. **Midwifery:** D. A. K. Cassells, C. R. Henderson, S. S. Ogilvie, Blanche D. S. Spence, Janet O. Stephen, W. Thomson, T. Wilson.

## UNIVERSITY OF LIVERPOOL.

THE diploma in tropical medicine has been awarded to M. J. Cohen, A. C. Crawford, C. M. Gracias, W. A. Letham, and S. D. Riley.

## UNIVERSITY OF DUBLIN.

## TRINITY COLLEGE.

AT the Winter Commencements held on December 20th, 1922, the following degrees and licences in the Faculty of Medicine were conferred:

**M.D.—G. O. F. Alley, F. G. Robertson, \*J. P. de Villiers, \*H. V. F. F. Exner.**

**M.B., B.Ch., B.A.O.—R. R. Baker, C. E. Brunton, L. J. Coetzee, F. B. D'Arcy, H. C. Dundon, M. Galivan, B. Guck, Mary H. Harcourt, R. Hegy, G. E. Holmes, J. B. Horan, Florine I. Irwin, Ruth Lemon, C. G. R. McCaldin, G. B. E. McCrea, J. O'N. McKenna, D. J. Malan, I. P. Myers, M. G. J. Powell, V. Robinson, P. Samolsky, M. Schwartzberg, Charlotte A. Stuart, C. G. S. van Heyningen, D. M. Vellema, B. Vivier, J. D. Wicht.**

**Lic. MED. AND S.—A. W. Eksteen.**

\* In absentia.

## SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates passed in the subjects indicated:

**Surgery.—D. D. Anderson, G. K. Buttsworth, E. M. Chidson, H. Hirst, G. Rothaus, R. A. Walker, A. Weinger.**

**Medicine.—D. D. Anderson, G. K. Buttsworth, E. M. Chidson, \*L. A. Daly, S. Douglas, D. J. Dubash, \*M. P. Parker, P. D. Richards, \*E. W. Turtle.**

**Forensic Medicine.—A. H. Allam, D. D. Anderson, L. A. Daly, M. P. Parker.**

**Midwifery.—D. D. Anderson, B. Dous, S. E. Hymans de Tiel, C. F. Parry.**

\* Section I. † Section II.

THE diploma of the Society (L.M.S.S.A.) was granted to the following candidates entitling them to practise Medicine, Surgery, and Midwifery: D. D. Anderson, E. M. Chidson, B. Dous, D. J. Dubash, C. F. Parry, P. D. Richards, G. Rothaus, and A. Weinger.

## The Services.

## DEATHS IN THE SERVICES.

Major Satyachara Pal, Indian Medical Service, died at Chittagong on October 7th, 1922, aged 40. He was born on December 24th, 1881, and educated in the Calcutta Medical College, after which he took the Scottish triple qualification in 1906. He entered the I.M.S. as lieutenant on February 1st, 1908, became captain after three and major after twelve years' service. He was serving in civil employment in the province of Bengal.

Captain Norman Edward Packer, R.A.M.C., died at Cologne, on October 25th, 1922, aged 31. He was born on June 13th, 1891, and educated at Sydney University, where he graduated M.B. and Ch.B. in 1915. He took a temporary commission as lieutenant R.A.M.C. on March 23rd, 1915, was promoted to captain after a year's service, and on April 1st, 1919, was confirmed as captain in the corps, ranking from September 23rd, 1918.

The Order of the British Empire conferred A.M.S., announced in the *London Gazette* on the recommendation of the Secretary of State for War, been transferred to the Military Division of the Order.

## Medical News.

THE scheme for the administration and staffing of the Maudsley Hospital provides for the employment of consulting surgeons and for an expenditure of £500 a year in payment of fees and expenses, including the cost of any dental work necessary. The London County Council has now proposed that the number of consultants shall be five—namely, a surgeon, a gynaecologist, an ear, throat, and nose surgeon, an ophthalmic surgeon, and a dental surgeon—and that the honorarium in each case shall not exceed £100 a year.

SIR AUCKLAND GEDDES, G.O.M.G., M.D., the British Ambassador, recently opened with an address the local cancer week held at Washington. An announcement was made to the effect that Mr. Albert D. Lasker, chairman of the United States Shipping Board, had made a donation of 25,000 dollars to the American Society for the Control of Cancer, in recognition of the excellent work that has been done by the Washington Committee.

THE Prince of Wales has appointed Lord Dawson of Penn, G.C.V.O., K.C.M.G., C.B., M.D., Sir Thomas Horder, M.D., and Dr. John Weir, to be Physicians in Ordinary to His Royal Highness; Sir Hugh Rigby, K.C.V.O., M.B., F.R.C.S., to be Surgeon in Ordinary to His Royal Highness; and Sir F. Stanley Hewett, K.C.V.O., M.D., to be Surgeon-Apothecary to His Royal Highness and his household.

PERIODICALS which purport to enlighten the lay public to a greater or less degree upon matters of medical interest are not unknown either in this country or in America, but the new monthly magazine *Hygeia*, which is shortly to be published by the American Medical Association, is in a somewhat different category. It is designed to appeal to the medical practitioner as well as to the layman, to serve as a link between the organized medical profession and the general public, and to keep the public in touch with the advances that scientific medicine is making in the prevention and alleviation of disease. Its contents are to include original contributions by leaders in public health and scientific medicine, as well as editorial comments. Authoritative information is to be given in replies to questions of general interest, and a section "for the children" is announced, written "in language they can understand." The magazine is to be illustrated and will contain summaries of literature and reviews of books, with a column of humour depicting "the lighter side of health problems." There are many difficulties to be overcome by this new venture. For instance, those scientists whose knowledge is greatest are not always those who can best place a scientific subject suitably before a lay audience. Again, for the understanding of any explanation of the processes of the disease a certain fundamental knowledge of the essentials of the anatomy or physiology is necessary. There is, however, evidently a demand to-day by the lay public for enlightenment on medical science, since even in this country many newspapers think it desirable to have a "medical correspondent" on the staff.

DR. W. KEEN, district medical officer for Chelsea, has just completed fifty years of service with the Chelsea Board of Guardians. Dr. Keen was educated at St. George's Hospital, and took the diplomas of M.R.C.S.Eng. in 1866 and L.R.C.P. Lond. in 1867.

THE annual general meeting of the Harveian Society will be held at the rooms of the Medical Society of London, 11, Chandos Street, Cavendish Square, on Thursday, January 11th, at 8.15 p.m., when the election of officers for the forthcoming year will take place and the president, Sir Wm. Willcox, K.C.I.E., will give an address. A smoking concert will be held at the end of the meeting.

DR. JOHN C. D. IRVINE, who recently resigned the office of parochial medical officer, Muthill, has been presented by his friends and patients with a chiming clock and cheque for £275, as a token of their respect and esteem, and in appreciation of his services to the parish for over thirty-two years.

AN outbreak of cholera began in the province of Chiba in Japan on September 29th, 1922, and by October 7th there were 107 deaths. The disease spread along the coast, and by October 10th there were 44 deaths in Tokyo.

OF the 17,350 medical officers who were employed in the German army during the war, 1,783, or 10.2 per cent., were killed or died of illness; 4,696 members of the sanitary corps were killed, and 157 died of disease; 5,722 stretcher-bearers were killed, and 786 died of disease; 28 nurses were killed, and 560 died of disease; and of the chaplains, dispensers, voluntary nurses and sisters, 9, 9, 16, and 8 respectively were killed.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2. on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### THE STING OF THE NETTLE.

DR. SHEFFIELD NEAVE (Ingatstone) asks to be informed of the nature of the irritating substance introduced by the sting of the common nettle. Formic acid has been mentioned, but apparently, Dr. Neave thinks, on insufficient grounds. He is led to make the inquiry by the result obtained in a difficult case of Raynaud's disease in the fingers of a patient who also has rheumatoid arthritis in the same parts. He found considerable benefit in the application of stinging nettles, which appear to administer the exact kind of counter-irritation and dilatation of capillaries advisable.

#### INCOME TAX.

"S. J. H." uses his motor-car occasionally for private purposes; the local inspector has deducted £30 from the expenses claimed.

\* \* In view of the small extent of the private use, it would seem that the life of the car and its replacement cost would not be affected. In that case the only additional—that is, non-professional—expense incurred would be the running costs for the short journeys and occasional rides to which "S. J. H." refers. We suggest therefore that he estimates the petrol and tyre cost of that private use per annum and objects to any deduction from the expenses claimed by him in excess of that amount. He has a right of appeal from the decision of the inspector to the District Commissioners or the Commissioners for Special Purposes.

### LETTERS, NOTES, ETC.

#### CANCER OF THE SCROTUM.

DR. J. S. PEARSE (Plymouth) writes: The article by Mr. A. H. Southam and Mr. S. R. Wilson (November 18th, p. 971) reminds me of a clinical lecture, given about thirty years ago by the late Mr. George Lawson at the Middlesex Hospital. He said that the sweeping of chimneys was not the reason or cause for a sweep developing cancer of the scrotum, but the fact that the men sifted the soot after removal to their own establishments before disposing of it. It was the method of sifting that caused the soot to get inside the clothes and thus set up the irritation. It is very seldom nowadays that a sweep sifts the soot, hence the small number of cases of chimney sweeps' cancer. At the same lecture Mr. Lawson said he made a practice of giving arsenic to cancer patients after operations for removal of the neoplasm. He was not able to give any definite explanation for so doing, except that he held the view or the impression that arsenic would prevent or control any recurrence of the disease.

#### A CASE OF SMALL-POX ARRESTED AND CURED BY VACCINATION.

DR. J. A. BENSON (Green Hammerton, York) writes: In the early seventies in the suburbs of a large Midland town my father, the late John Benson, M.R.C.S., L.S.A., was called to see a domestic servant who was in the services of Lady B—, and found the maid in a state of fever and broken out with a well marked small-pox rash. No. 2 maid had been sleeping with her in the same bed. Lady B— was expecting a large house party in about three weeks. The small-pox case was immediately isolated in a distant lodge in the grounds and her bedroom recently occupied was fumigated and cleaned. No. 2 maid was placed in quarantine in another lodge in the grounds. Sir John and Lady B— and the whole household were all vaccinated, including No. 2 maid, who was suspected of being in the incubation stage of the disease. The case of No. 1 maid ran its

usual course and she recovered in due time. On the third or fourth day after vaccination No. 2 maid broke out and became covered with the small-pox rash. On the fifth or sixth day after vaccination it began to take, and as it developed the small-pox died away, and in a very short time, and long before No. 1 maid this patient was perfectly cured. No other cases occurred, and the house party was permitted to arrive and depart, and were none the wiser and none the worse. In later years my father told me of this case, which to his mind was a remarkable one, and he often regretted that he had never reported it to the BRITISH MEDICAL JOURNAL.

#### "B.P.C." BANDAGES.

In March, 1922, the Council of the Pharmaceutical Society of Great Britain published a Supplement to the *British Pharmaceutical Codex*, 1911, relating to surgical dressings. The section on bandages (ligaments) lays down the requirements for the nine varieties of "B.P.C." bandage. In respect of crêpe bandages these requirements are set out as follows:

"Normal length.—2½ to 2¾ yards.

"Extension.—Length, when fully extended, to be not less than twice the normal length. To contain not less than 33½ per cent. by weight of wool, the remainder of the fabric to be of cotton."

This is intended to ensure a certain standard of elasticity, and also a definite minimum length when the bandage is delivered to the customer. We understand that foreign bandages are now being offered for sale in this country which do not comply with the requirements laid down in the Supplement to the *Codex*. Medical practitioners would therefore be well advised to buy only bandages manufactured by reputable firms, and where "B.P.C." bandages are desired to insist upon a guarantee that the requirements set out in the Supplement are fulfilled. We are informed that Messrs. Grout and Co., Ltd., of Great Yarmouth, manufacturers of the Norvic crêpe bandage, give this guarantee, and we have no doubt that other leading makers would be willing to do so.

#### OFFERS OF MOTOR SPIRIT.

DR. H. E. MCCREADY (74, Middleton Hall Road, King's Norton, Birmingham) writes under date November 28th: A man giving the name of C. G. Ward, and representing that he is travelling for the National Benzol Company, Newcastle-on-Tyne, is calling upon doctors and obtaining various sums of money from them by offering spirit for sale and asking for cash in advance—this man is wanted by the police for similar offences in different parts of the country. He now appears to be specializing on doctors; should he call on any of the doctors, if they will detain him and immediately inform the police of their district—who will take the necessary steps for his arrest—by so doing they will render the profession a service. The following is a description: Age 45; about 5 ft. 9 in.; fresh complexion, grey eyes, clean shaven, bald, smart appearance, and usually carries an attaché case with all the usual motor literature and advertisements.

#### THE LONG UNLOVELY STREET.

A CORRESPONDENT suggests that Tennyson's "long unlovely street" must be Wimpole Street and its continuations, not Harley Street, for it was in Wimpole Street, apparently in the part called "Upper" that Arthur Hallam's father lived. Our correspondent admits that *Wimpole and Harley Streets* are very much alike and does not contend that the latter is beautiful.

#### STALACTITES.

DR. A. G. C. POCOCK (Shotley Bridge) writes: The following anecdote of a consultation with a patient's mother may amuse: "I advise you to rub a little of the ointment into the back each night. You know the Latin proverb, which runs: *Gutta cavat lapidem non vi sed sæpe cadendo*." I translated this to her and she replied: "Oh yes, doctor, I know the stalactites."

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 12.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429 Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

## A British Medical Association Lecture ON SOME CLINICAL MANIFESTATIONS OF TABES DORSALIS.

DELIVERED TO THE HARROGATE BRANCH, OCTOBER 7TH, 1922,

BY

GORDON HOLMES, M.D., F.R.C.P., C.M.G., C.B.E.,

PHYSICIAN TO OUT-PATIENTS, NATIONAL HOSPITAL; ASSISTANT  
PHYSICIAN, CHAMBER CROSS HOSPITAL.

THERE can be little doubt that no nervous disease presents itself under so many and varied manifestations as tabes dorsalis; perhaps no other affection of the body assumes so multifarious forms, and the experience of my own practice is that in no other condition is my help in diagnosis more frequently asked by general practitioners and by other specialists. I have consequently selected as my subject some of the clinical manifestations of this disease, and will deal chiefly with those which offer difficulties in diagnosis. These are usually early or isolated symptoms. Time will, unfortunately, prevent any but a cursory reference to the pathology of the disease or to the pathogenesis of its symptoms, and even the question of treatment must be largely neglected, conscious though I am that to those engaged in the daily care of patients treatment must demand the foremost place in the discussion of any disease. My excuse is that in tabes diagnosis must precede efficient treatment.

### *Tabetic Pains.*

Pains are notoriously among the earliest and most common symptoms, but they are by no means constant, for even the most careful questioning of some patients fails to elicit a history of any. There can be rarely any doubt of their origin when an accurate description of their nature is obtained, since the shooting, lancinating, or lightning pangs, or the sharp darting or burning stabs, often compared to red-hot needles, which shift from place to place, are almost typical. The difficulty in recognizing them occurs when their character or the description of them obtained is less typical, and especially when, being an early feature of the disease, it is for their relief only that the patient seeks our advice.

The proportion of early tabetics who first complain of "rheumatism," or, using the term made popular by the war, call their trouble "myalgia," is certainly considerable, and in many of these the knee-jerks are still present, the pupils react to light, and there is often no disturbance of gait. The features that should attract our attention are the reference of the pains to the muscle masses, or to the tissues between rather than around the joints, and the fact that they are usually neither excited, aggravated, nor otherwise influenced by movement or by pressure as rheumatic and myalgic pains are. Further, these early pains frequently occur in the trunk, where rheumatic pains are rare, or trunk pains appear simultaneously or alternately with limb pains.

In many cases where the pains are limited to a small region the diagnosis of "neuritis" is made, or they may be attributed to "sciatica" when they occur chiefly on the posterior aspect of the lower limbs. But if we have an intelligent patient, or can obtain an accurate history, it is usually easy to exclude a neuritis. In the first place the pains are rarely, if ever, limited to the distribution of the sciatic or any other nerve, and if they happen to be they spread over a small part only of its sensory area and do not follow its whole course; if they occupy the sciatic region they generally occur in other parts of the limb too, or in the opposite limb, or in the trunk, which is, of course, exceptional in sciatica. Further, in neuritis and sciatica the affected nerves are tender or at least sensitive to pressure and stretching, while in tabes they are usually completely or abnormally insensitive, as Biernacki pointed out.

It is, however, pains limited to certain regions that are most likely to confuse us or lead us into error. While the description of a typical girdle pain around the waist or thorax arouses our suspicions at once, we are more likely to overlook the origin of a pain which is more or less constant and fixed in one side of the abdomen or chest, seeking its explanation in some disease or disturbance of the underlying visceral organs. But such local pain is common in tabes, and is often an early symptom. Here again the nature of the pain and its distribution are valuable guides. As a rule the tabetic pain is not

limited to an area on any aspect of the trunk as visceral pain usually is, or though it may be greater at one point it tends to spread around the whole distribution of those sensory roots to the disease to which it is due. But this is not always a characteristic feature, since girdle or semi-girdle pain is often associated with visceral disease; we are all familiar, for instance, with the pain which encircles one side of the lower thorax and abdomen in basal pleuropneumonia, and the radicular hyperaesthesia of Head and McKenzie associated with disease of deeper organs is often described as pain. The absence of evidence of such disease is, of course, an important point in diagnosis, but still more is the fact that in tabes the pain is not accompanied by those manifestations which one would expect were it due to an affection of a visceral organ. Pain referred to the abdomen, which we might attribute to the appendix or gall bladder, is, for instance, not associated with tenderness or resistance over these organs, and that in the thorax is not aggravated by deep breathing nor associated with limitation or alteration in the respiratory movements. Further, the patient's conduct and activity are not, as a rule, compatible with visceral disease of sufficient intensity to produce such pain, for the tabetic often continues to lead an active life, or shows at least little reluctance to move, though he complains bitterly of his sufferings.

The possibility of tabes must be therefore always considered when, on the one hand, movement or the functional activity of the organ suspected does not aggravate or increase in any noteworthy degree a severe and persistent pain, and on the other when pressure or handling of the parts to which it is referred has little or no influence on its severity. But caution is necessary in applying these tests, since the skin of an area where tabetic pains have persisted for some time often becomes unnaturally sensitive to certain forms of stimulation at least. It is most commonly excessively tender to moving stimuli, as to a hand or even a wisp of cotton-wool drawn over it, but then heavy pressure or a pin-prick may give no discomfort, or indeed less than it would on normal parts.

This observation leads us to the most important point in its differential diagnosis, which is that where tabetic pain has persisted for any considerable time there is a disturbance of sensation, most commonly a reduction of pain sensibility. The suffocating tightness around the thorax or the abdominal girdle pain occurs, as is well known, in areas of analgesia or hypalgesia, and the same general rule holds for pain of other distribution. It is, in fact, rare to find all forms of sensation intact where pain is severe, except in a small proportion of those cases in which it is recent.

These sensory disturbances are almost invariably the only objective or demonstrable changes associated with tabetic pains. Occasionally, though very rarely, the existence of pains in one region of the body is followed by changes in the skin; I have seen subepidermal haemorrhages in limbs that had been subject to prolonged local pains, and in one case repeated outbursts of herpetic vesicles. A local falling of hair and thinning and atrophy of the skin have been also described.

The frequency of local pains in the limbs, and particularly in the trunk, is generally recognized, but such local pains occurring in the head have attracted less attention. They are not prominent symptoms in a large proportion of the cases, but are yet sufficiently common to warrant notice. I have, for instance, seen more than once recurring tabetic pains in the cheek diagnosed and treated as trigeminal neuralgia, and one of my patients had even undergone alcohol injections for this condition, though careful questioning would have revealed the true state and obviated a therapeutic failure. But more common than facial pain is pain of either sharp and stabbing or dull and aching character, limited to or most pronounced in the occipital region of the scalp; it is therefore likely to be confused with occipital neuralgia. When an isolated complaint the origin of these pains may not be easily recognized, but a careful history generally discovers the existence at some time or other of more or less similar pains elsewhere, and examination brings to light other signs of the disease, for these facial and occipital pains are rarely early or isolated symptoms. When tabes is suspected their nature can be assured by even a cursory examination of sensation, for, as is the rule elsewhere, pain sensibility is absent or diminished where they occur, though tactile and probably other forms of sensation are intact or little disturbed.

Not infrequently it is not for the relief of pains that the patient consults us, but owing to the existence of an unnatural sensitiveness or tenderness of some part of his body to stimuli

which normally give little or no discomfort. Those accustomed to the routine examination of patients with nervous complaints are familiar with the excessive reaction and violent expostulations that even gentle scraping of the soles in eliciting the plantar reflex may evoke in a tabetic. Sometimes there is a similar hyperaesthesia to other stimuli, as the rubbing of the clothes on the trunk and limbs. Unnatural sensitiveness to thermal stimuli, and especially to cold, is more common. The touch of a cold hand may be resented, and a few drops of cold water sprinkled on the trunk, particularly on the back, may evoke intense burning or stabbing pains. This is occasionally one of the first symptoms of the disease. I lately saw a doctor suffering with tabes who discovered three years before any other symptoms appeared that he could no longer swim or take a cold bath, since immediately the water reached his waist he experienced what he described as "an awful feeling as if his body were being cut through by red-hot knives." Some of these patients come under observation complaining of rheumatism or neuralgic pains, which are excited or aggravated by a draught of cold air or by contact with any cold object.

#### *Paraesthesiae.*

Another important group of symptoms are the various paraesthesiae so common in tabes. Sometimes it is a complaint of numbness or loss of feeling; sometimes it is of a "uselessness" of the hands or feet, to employ a vague description often used by the patients; more rarely it is a distressing sensation of either heat or cold, or a feeling of dampness or wetness of some part. The difficulty in recognizing the nature of these symptoms is due mainly to the fact that objective changes corresponding to the loss or perversion of sensation of which the patient complains cannot usually be demonstrated by a casual examination. Though he may tell us that he does not feel the ground properly under his feet, that it seems to him as if he were walking on air or on soft cushions, we may find tactile and perhaps other forms of cutaneous sensibility on his feet unaltered, and we may consequently conclude that there is no organic basis for his complaint. But, as Hughlings Jackson pointed out, the sensation of resistance or the recognition of the consistence of objects, as the hardness of the floor, depends not on cutaneous sensation but on those afferent impressions which arise from the deeper structures of the limbs, especially from the muscles and tendons. The feeling of "uselessness" in the hands also is due mainly to disturbances of the sense of position, or of the power of recognizing the form and weight of objects handled, rather than to loss of cutaneous sensibility.

There is often, however, some disturbance of skin sensation too. In a patient under my care one of the first symptoms was inability to "feel" his billiard cue properly, which seemed at first inexplicable, as tactile, pain, and thermal sensibility on his fingers were intact. Later the "loss of feeling" increased so much that he had to cease dining out since he could not use his knife and fork properly, and since he could not "feel" the coins in his pocket he could take a taxi only when accompanied by a friend; but still there was little or no insensitiveness of the skin to the ordinary tests. A more complete examination revealed, however, great impairment of the sense of position in his fingers, and that he was unable to recognize accurately the shape, size, and weight of objects placed in his hands. Since it is to disturbances of these qualities of sensation that similar disorders are due in other spinal and cerebral diseases as well as in tabes, a careful investigation, particularly of the sense of position, is essential in attempting to elucidate their nature.

This numbness or subjective loss of feeling is occasionally found in unexpected parts; I have seen a few patients whose chief complaint was that their penis and scrotum felt numb or dead, and in one man at present under my care the most distressing symptom is that he has no feeling in his lips and cheeks.

#### *Tabetic Crises.*

Next in order after pain it is the tabetic crises that are most likely to offer difficulties, or to lead us into error in diagnosis. We are all familiar with the patient on whom perhaps several abdominal operations have been performed without giving the promised relief. I recently saw two patients on successive days, one of whom had undergone four and the other five abdominal explorations for attacks of acute abdominal pain and vomiting. The appendix or the gall bladder may be suspected, or the symptoms may suggest perforation. A neurologist may easily exaggerate the frequency with which this mistake is made, but that it is not

uncommon is shown by the experience of an American colleague lately working with me. He obtained permission to investigate patients on whom abdominal operations for acute symptoms had been recently performed in several general hospitals, and he discovered among them a proportion of tabetics subject to gastric crises much larger than I would have believed possible. Gastric crises probably occur in about 10 per cent. of all tabetics.

Here, as is the case in tabetic pains, the errors in diagnosis can be attributed largely to the fact that these crises are frequently early symptoms, and are often not accompanied by those signs that are commonly held to be characteristic of the disease. Many patients, in fact, state that apart from the abdominal attacks they enjoy perfect health.

We can as a rule gain little information of value from the patient, as the pain and the character of the vomiting resemble closely those due to intra-abdominal conditions. The pain, which generally precedes the vomiting, commences in the epigastrium, but later radiates into the back and spreads throughout the whole abdomen and into the loins; it is usually of an intense burning or violent cramp-like character, and is generally accompanied by sensations of constriction or distension. The vomiting which soon sets in may be more or less continuous for days, and may or may not be associated with nausea. The points which should arouse our suspicions that the pain and vomiting are of nervous origin are, in the first place, the history that similar attacks have occurred before, each of which ceased more or less abruptly and left the patient in apparently perfect health. But this is not a pathognomonic feature, since renal and biliary colic may also recur between periods of normal health, and it is when we are so unlucky as to meet with a patient in the first crisis that our difficulties are greatest. In the second place the most striking feature of a tabetic crisis is that, though the patient vomits incessantly and gives evidence of the most intense pain, the abdomen between the bouts of vomiting is lax, or at least not so resistant as it would be with an acute visceral lesion, and handling or palpation does not notably increase or excite the pain. But here too we must be on our guard, since the vomiting is often accompanied by intense hyperaesthesia of the skin; the first touch of the hand, and particularly gentle stroking, may evoke at once great discomfort and excite a reflex contraction of the muscles. But when the hand is laid firmly on the abdomen this tenderness disappears, and deep palpation can be often carried out without discomfort to the subject and without exciting muscular contractions; this is the most valuable diagnostic feature of tabetic vomiting.

Not infrequently patients complain not of the characteristic paroxysms of pain and vomiting, but of a constant nausea or aching in the region of the stomach. In these the symptoms are likely to be treated as merely manifestations of dyspepsia, but it is usually found that neither the nausea nor pain bears any relation to food, and that they do not yield even temporarily to change or restriction of diet, or to those drugs by which we treat dyspepsia or the conditions to which it is ordinarily due. Further, the appetite usually remains surprisingly good despite the discomfort, and there are no objective signs of gastric disturbance.

Laryngeal crises are probably the next most common variety. They, too, may give rise to errors in diagnosis. The most common form begins with tickling or a feeling of constriction in the throat, followed by a violent paroxysm of coughing, accompanied in severer attacks by dyspnoea and stridor, continuing till the patient becomes asphyxiated or even semi-conscious. An accurate description will probably indicate their nature at once, but unfortunately accurate descriptions, unless we elicit them by adequate questioning, are not common. The patient's complaints may consequently suggest either a local laryngeal disturbance or an attack of asthma; the latter is likely to be suspected, since laryngeal crises occur most frequently at night. Unless the signs of tabes are sufficient to attract attention or to indicate the diagnosis the conclusion must be based on negative rather than on positive evidence. Laryngoscopic examination reveals nothing to account for the attacks, or at the most an abductor palsy, while examination of the chest shows none of the signs usually associated with asthma.

Rectal crises, characterized by paroxysms of local pain, with distressing tenesmus, and often with the sensation of a foreign body in the rectum, are rarer, but I have seen them give rise to serious mistakes in diagnosis. Here, again, the absence of signs of local disease, the persistence of the symptoms over long periods, and the fact that the pain often

radiates more widely into the perineum and surrounding parts than it does in rectal affections, must put us on the search for a nervous origin of the complaint.

#### *Bone and Joint Lesions.*

The next group of symptoms that are perhaps most important to those engaged in the general practice of medicine are the bony and arthritic lesions which are so common in tabes. Fractures of the long bones, especially of the femur, may occur as a result of a trivial injury, or even of muscular action. The fact that there is often little or no pain may lead to failure to detect the true nature of the condition, and the difficulty in obtaining proper union may be, in the light of recent legal decisions, a serious matter for the surgeon who is so unlucky as to meet such a case. I obtained recently an autopsy on a woman whom I had followed for several years. About twenty years ago she slipped in the street, and, being unable to rise, was taken into hospital. There a fracture of the right femur was detected, and, according to her own story, the left femur was inadvertently fractured too, during the manipulations to set the broken limb. As a result she never rose from bed again. At the *post-mortem* examination I found both femora fractured, the broken ends widely separated and eroded, and enclosed in dense fibrous cysts. These fractures often occur under unsuspected conditions. Several years ago, while resident in a hospital, I was asked to see a charwoman employed there, who, while at her work immediately before, suddenly developed an enormous swelling of the right shoulder, with subcutaneous haemorrhage, which eventually tracked over that side of the thorax and down the arm. Examination revealed a fracture of the upper end of the humerus, which had apparently occurred without any pain; the haemorrhage was probably due to the jagged end of the broken bone having torn one of the large vessels in its neighbourhood. This woman's husband had died with tabes several years previously, but she had believed herself in good health, and even questioning failed to elicit any previous symptoms of the disease apart from a little 'rheumatism.'

The arthropathies are much more common, and are often the first symptom that brings the patient to notice. It is unnecessary to refer to the more or less characteristic features of these lesions, which were so accurately and vividly described by Charcot, but there are a few points in connexion with them which are of general interest. The first is their relation to injuries often so slight that they are disregarded by the practitioner who is called in, though emphasized by the patient, who is always on the look-out for an extraneous causal factor for his troubles. A slight strain at the knee or ankle is followed by a more or less painless swelling which persists longer than the nature of the injury appears to warrant, and is succeeded by disintegration of the joint, laxity of its ligaments, and the well-known deformities. It is often only when this stage is reached that the real nature of the condition is recognized. In fact the only feature which, as far as I am aware, may in the early stages excite suspicion is the painlessness of the swelling, but even this is not pathognomonic. Arthropathies in the limbs are generally easily recognized, but those which occur elsewhere may escape detection. A few months ago, for instance, a man was sent to me owing to a swelling in his lumbar region which obviously involved the spine. A vertebral tumour was suspected, the existence of which would have explained the absence of his knee-jerks, as the lumbar roots would have been certainly involved. It was only further examination of the patient which showed he was suffering with tabes, and the painless nature of the deformity then made diagnosis clear.

The arthropathies sometimes follow more serious injuries. Some time ago I saw a woman who, while in apparently good health, had twelve months previously sustained a Pott's fracture of her left ankle owing to a fall. The bones did not unite as would have been expected, and the swelling about the ankle-joint increased rather than diminished. When I saw her there was a typical Charcot lesion with considerable absorption of the lower fragment of the tibia and disintegration of the joint.

Among the so-called trophic disturbances the painless chronic and indolent perforating ulcers which occur on the soles need no comment; the only other condition in which they are commonly seen is diabetes, but they are in this disease, in my experience, usually associated with more pain or discomfort. It is, however, worth while bearing in mind that they are not limited to the sole; I have seen one on

the stump that bore an artificial leg, and one on the inner side of the cheek where a denture rubbed. Falling of the hair is less common, but lately a man under treatment for alopecia was referred to me as he complained of rheumatism; examination showed he was a typical tabetic who had almost suddenly and without apparent cause lost all his hair. Rapid loosening and falling out of the teeth is also sometimes seen.

#### *Sphincter Disturbances.*

The sphincter disturbances of tabes are another pitfall to the unwary. We all recognize the frequency of either retention or incontinence of urine in the advanced stages of the disease, but often forget that these may be among its earliest manifestations. Not infrequently I see patients who have been under treatment for local vesical troubles, or who have even undergone operations; it is consequently worth our while to consider shortly the more common forms that these bladder symptoms assume. The earliest change is generally slowness in starting the flow of urine; the patient has to wait an unnatural time before the urine comes and may have to use accessory means, as pressure over the bladder, to start it. Further, the bladder is often not completely emptied, so that a considerable amount of residual urine may be found immediately after micturition. In a man over middle age these symptoms may, of course, suggest an enlarged prostate or a stricture. Frequently occasional incontinence occurs at this stage too, the urine dribbling away in a few drops at a time, especially at night or on a sudden exertion, often unperceived by the patient, since the urethra and penis may be anaesthetic. In other cases there is a chronic distension of the bladder which may be unnoticed, since it is frequently insensitive to that degree of tension which normally produces pain or discomfort.

Rectal troubles are less common, but I have seen incontinence occur as an early symptom, occasionally the passage of faeces not being noticed by the patient owing to the anaesthesia of the anal region. As the sexual power is generally lost in males early in the disease, the possibility of tabes must be also considered in every case of impotence. Since the sexual appetite usually disappears at the same time it is not a matter of such distress and worry to the tabetic as impotence due to other causes usually is.

#### *Ocular Symptoms.*

One other group of symptoms to which I shall refer are the ocular troubles which occur so frequently in the course of tabes. Certainly the majority of patients afflicted with this disease have at some time or other during its course diplopia due to paresis of one or more of the ocular muscles. The external rectus is the muscle most commonly involved, especially in the early transient palsies, and next in frequency those supplied by the oculo-motor nerve.

There is nothing characteristic in either the form or course of these ocular palsies, and their origin can be consequently determined only when the disease is diagnosed. In many cases they are transient, disappearing within a few days or weeks; in others they are permanent and resistant to treatment of every form. Frequently the degree of dislocation of the visual axes is so slight that no squint can be observed, and the patient may complain of blurred or indistinct sight rather than of double vision. This is occasionally a source of confusion, since a disturbance of refraction may be suspected, or, the sight of each eye alone being good, the origin of the defect may be obscure.

Ptosis, or drooping of the eyelids, may, of course, result from a lesion of the trunk of the oculo-motor nerve, or it may appear as an isolated symptom apart from palsy of any of the external ocular muscles. It is on the latter variety that I wish to lay emphasis, since it is an important diagnostic sign. There are, in fact, few cases who do not present it in some degree. The upper lids droop equally, or the one perhaps more than the other, but at first they rise to the full extent, or almost so, when the patient looks up. In order to compensate it the frontalis muscle is permanently contracted, and the forehead is therefore wrinkled. Largely to this is due the 'tabetic facies' by which many cases can be recognized at the first glance; other factors in this typical appearance are the small pupils and the curious moist glistening eyes. So characteristic is this facies that one familiar with it can almost always pick out tabetics lying in a ward with, or sitting among, other patients.

It is also necessary to insist that though failure of the pupils to contract to light is regarded as one of the most characteristic signs of the disease it is not invariably present

in tabes, nor is it the only pupillary anomaly that occurs. The Argyll Robertson sign—that is, miotic pupils which fail to react to light but contract on accommodation—is probably seen in not more than 60 per cent. of the cases. In others the pupillary apertures may be normal in size, or those of the two eyes may be unequal, and not infrequently the pupils fail to contract on convergence too. In the latter case there is often a disturbance of accommodation; being a physician to a large ophthalmic hospital I often see patients complaining of defective vision due to palsy of accommodation, in whom examination reveals no cause other than tabes.

It must be borne in mind that though tabes is the condition in which the Argyll Robertson phenomenon is most commonly seen, it is not pathognomonic of this disease. There can be no doubt that it may result from local lesions of the mid-brain, and that it occurs occasionally in syphilitic subjects who never develop tabes; according to some authors it is found in uncomplicated cases of chronic alcoholism.

Finally, the frequency with which tabes is the cause of blindness or diminution of vision due to primary atrophy must not be forgotten. At the Royal London Ophthalmic Hospital a large number of cases with diminishing vision and the ophthalmoscopic appearance of primary optic atrophy are referred to me, and in a considerable proportion of these the neurological diagnosis is tabes. That the proportion is really larger than the physical signs at the moment of examination indicate I have no doubt, since the onset of blindness is frequently the first and the only sign of the disease. It is therefore worth bearing in mind that about 20 per cent. of all tabetics develop optic atrophy, and that tabes is a very common disease. Consequently, we can never afford to neglect the possibility of tabes in any patient who in adult years complains of failing sight.

#### DIAGNOSIS OF TABES.

As we have not considered some of those symptoms of tabes that may present difficulties in diagnosis, we must turn to the means by which diagnosis can be most accurately made.

The first question that arises is, What is tabes? Are we justified in making this diagnosis in patients with isolated symptoms, each of which may be due to other causes?—when, for instance, a man complains of pains in his legs and examination discovers only diminution of one knee-jerk; or when another has a primary optic atrophy and gives a history of transient diplopia, but presents none of the other so-called cardinal signs; or when Argyll Robertson pupils are the only demonstrable abnormality; or when we find a painless, swollen, and disintegrating joint, and loss or diminution of some of the reflexes. It may be easy to answer this question in any specific case, but it is certainly difficult to make a general rule. Even the pathological and serological tests are not conclusive, as they often are negative in patients with characteristic symptoms, and especially in slowly progressive cases in which the symptoms are not typical. Indeed, a positive Wassermann reaction is obtained in the blood in not more than 65 per cent. of all cases, and it may be negative even in the cerebro-spinal fluid, and the latter may show no other pathological changes in 20 per cent. If we therefore rely on the clinical pathologist we are liable to an error of 1 in 5 at least.

A short review of the pathology of the disease may help us. The most obvious anatomical change is a degeneration of the posterior columns of the cord. The older views that this is the primary lesion have been conclusively disproved, and all now agreed that the spinal degeneration is secondary to disease of the posterior roots. But the nature of this primary affection is not yet conclusively settled. According to one hypothesis it is a primary degeneration of the fibres of the posterior roots due to the selective action of a syphilitic toxin upon them; according to another the main factor is injury of the roots by an overgrowth of connective tissue which surrounds and constricts them. All recent evidence points to the latter hypothesis as being the more probable. Some years ago Nageotte insisted that the essential lesion is to be found where the posterior root joins the anterior root before they reach the ganglion. This portion, which he calls "*le nerf radicaire*," is surrounded by a sheath of the arachnoid, and, according to him, in suitable cases it may be shown that the changes commence in the subarachnoid tissue around this portion of the root; they consist in the proliferation of granulation tissue, which, partly by interfering with the nutrition of the nerve fibres, partly by mechanical constriction of them,

leads to their degeneration. Nageotte's findings have been lately confirmed by Richter, who has in addition demonstrated the presence of spirochaetes in this arachnoid funnel.

Whether this theory of Nageotte and Richter ultimately proves to be true or not, there can be no doubt that the essential lesion of the disease is a degeneration of the posterior roots, and consequently the most constant and characteristic symptoms should be disturbances in the functions of the afferent systems. The knee-jerks and other reflexes depend on the integrity of this, and they are consequently usually absent in the advanced stages of the disease. But this is by no means so in the early stages, and in many cases they certainly persist for years after unequivocal signs have appeared. Further, Romberg's sign is by no means constant, especially in the early part of the disease when diagnosis is most important. Even the pupillary reflexes are often normal or the reactions are anomalous, and in quite a large proportion of all cases gait is never affected. We thus find that all the cardinal signs on which the ordinary textbooks of medicine lay so much stress may, like the clinical pathologist, leave us in the lurch.

When, however, we turn to the examination of sensation we find, as we might expect from the pathological site of the disease, that there are very few if any cases in any stage in which there are no sensory changes. But a complete examination of sensation is extremely difficult and time-consuming, and there are but few competent either by training or experience to carry it out. Further, the character and form of the sensory disturbances vary enormously from case to case. We must therefore for clinical purposes select tests that are simple, reliable, and practicable. And this is luckily possible, for the most constant and characteristic changes are in sensibility to cutaneous pain.

When sensation is tested with the point of a sharp steel pin or needle widespread disturbances are usually found even in the early stages of the disease. But even this simple test requires some care, as the insertion of a pin-point evokes, in addition to pain, an idea of sharpness by which the stimulus can be often recognized in analgesic areas, and unintelligent patients may consequently make replies that confuse the observer. This difficulty is obviated by placing the point of the pin against the tip of the observer's index or middle finger and pressing with the finger on the skin as the pin penetrates it; then the patient can be asked to reply whether each contact is only a touch, or if there is a prick as well.

The earliest loss of sensibility to pin-prick is usually found on the lower extremities; it is most marked on their distal segments, and diminishes gradually in intensity towards the groins. It does not as a rule correspond to root distribution; it may, for instance, be slight or absent on the thighs and buttocks though considerable in degree in the legs, which are innervated by the same sacral and lumbar roots. Sometimes, however, it follows the lines of the cutaneous root areas.

At first the loss is only partial—either the pain evoked by the stimulus is less than a prick produces elsewhere, or more commonly only a certain proportion of pricks of moderate intensity, but sufficient to cause pain in normal persons, are recognized. As the disease advances this hypalgesia becomes more intense. Not uncommonly patients appreciate no discomfort from a pin-prick on any portion of the lower limbs, or only in the upper thighs, but before this stage is reached certain anomalies of sensation are often present. There may be a delay in the perception of pain, or the prick excites abnormal sensations, as burning or tingling, or the pain persists unnaturally, so that the patient commonly attempts to "rub away the feeling."

Even more common than disturbance of pain sensibility on the legs is the zone of analgesia around the trunk, to which Laehr first drew attention. The upper margin of this zone generally lies at the level of the second ribs in front where the areas of the cervical and dorsal roots meet; it may extend downwards only a few inches or as far as the groins. As a rule the hypalgesia is most intense between the second ribs and the nipples, while the zone around the trunk immediately above the groins and buttocks is that which generally escapes longest. The loss of pain sensibility in this trunk zone is usually more profound than on the legs. When it is only partial it can be easily demonstrated by making a series of pricks from below upwards towards the clavicles or on to the neck.

Another common area of analgesia is the ulnar borders of the arms, but this usually appears later in the disease. It is variable in extent, and may be represented by a narrow

band in the inner border of the forearm, or may comprise the whole ulnar half of the limb, including the two or three ulnar fingers. Here too, as on the legs, the analgesia is rarely complete, and is often represented only by a relative insensibility as compared with the radial borders of the arms.

Duchenne observed many years ago that the face is occasionally analgesic in *tabes*, or rather that portion of it which is supplied by the trigeminal nerve. He spoke of this trigeminal loss as "*le masque tabétique*," but a complete mask is rare. Some diminution of sensibility to pin-prick is, however, extremely common on an irregular area in the centre of the face, especially on the nose and the neighbouring portion of the cheeks. It is an important symptom, as sensory loss of this distribution is not found in any other nervous disease, except perhaps leprosy. It is easily demonstrated, for probably on no part of the body is the prick of a sharp pin so painful as on the nose and adjoining portions of the cheeks, and it is exactly here that sensibility is often lost or diminished in *tabes*. The area affected may vary from a small patch on the nose to the greater part of the face, until indeed it forms a typical tabetic mask. If slight it may be apparent only when the sensibility is contrasted with that of a normal area, as on the neck.

The diminution, loss, or alteration of sensibility to pin-prick in some or all of these areas—that is, the distal portions of the lower limbs, the thoracic zone, the radial borders of the arms, and the central portion of the face—constitutes the most common, the most definite, and the most characteristic physical sign of *tabes dorsalis*. It is frequently present when the knee-jerks and the pupillary reactions are normal and before ataxia or other symptoms develop, and it is consequently a most important phenomenon in the diagnosis of the disease. The loss of sensation in these areas is a dissociated one—that is, its different modalities are affected in different degrees, or some forms only may be disturbed. Touch, for instance, is frequently intact on the chest and face at least, and the affection of thermal sensibility is inconstant and irregular. Its diagnostic value is enhanced by the fact that in no other disease is there dissociated analgesia of a similar distribution.

Though I lay so much weight on the presence of this cutaneous analgesia as a diagnostic sign owing to its constancy and the simplicity with which it can be demonstrated, I do not wish to underestimate the importance of other sensory disturbances. Tactile sensibility is rarely profoundly affected, but is often reduced, especially on the legs. Thermal sensibility is more irregular, and as the sensations evoked by the contact of hot and cold test objects may be perverted rather than reduced, its investigation is too difficult for ordinary clinical purposes. On the other hand, though changes in so-called deep sensation—that is, the sense of position and movement, the recognition of size, shape, and weight, and the appreciation of vibration—are certainly the most important in the pathogenesis of the symptoms of the disease, their investigation requires more care and skill, and disturbances in them are much less constant in the slighter cases and in the early stages.

Few diseases are so protean and irregular in their manifestations; few, if any, present so many symptoms that may lead us into error in diagnosis and prognosis, and few require in their early stages so much care in investigation and treatment. I have endeavoured to put before you some of the pitfalls that await us, for consciousness of danger is our surest safeguard, and to point out the simplest means by which, in my experience, we may avoid mistakes.

THE question of indirect advertising has been occupying the General Council of the Bar. The annual report for 1922 states that the attention of the Council was called to an article, which appeared with sensational headings in a Sunday newspaper, purporting to be written by a leading counsel. When asked for an explanation, this gentleman stated that the managers of the paper had pressed him to see a reporter and to give him his views on a legal subject. After several refusals the counsel ultimately acceded to the request, warning the reporter that the interview was not to be used in any way that might be regarded as advertising himself. The interviewer apparently worked up the conversation into an article, which appeared under the name of the counsel as if it had been actually written by him. Eventually the managers of the paper expressed regret for what had occurred. The General Council of the Bar, with a view to avoiding possible misunderstanding in the future, has passed the following resolution: "That it is contrary to the etiquette of the Bar for a practising barrister to give an interview to a representative of the press on any matter in which he has been or is engaged as counsel."

## SOME APPLICATIONS OF PHYSIOLOGY TO MEDICINE.

### I.—SENSORY PHENOMENA ASSOCIATED WITH DEFECTIVE BLOOD SUPPLY TO WORKING MUSCLES.

BY

J. A. MACWILLIAM, M.D., F.R.S.,

PROFESSOR OF PHYSIOLOGY,

AND

W. J. WEBSTER, M.B.,

ASSISTANT IN PHYSIOLOGY, IN THE UNIVERSITY OF ABERDEEN.

(From the Physiological Laboratory.)

ACCURATE knowledge of the effects of defective blood supply to the various tissues and organs is obviously of great importance in view of the innumerable conditions of stress, derangement, and disease in which this factor comes into play, with manifold results in the way of disturbed or impaired functions in the different systems of the body. "Defective supply" naturally covers different conditions—quantitative deficiency in normal constituents, or the presence of abnormal and injurious constituents, or inadequacy as regards the volume, pressure, and rapidity of flow of normal blood. This communication deals with the last-named—certain effects of deficiency in the supply of normal blood to normal muscles.

Many impairments of functional activity from more or less extensive interference with blood supply have long been known, such as the weakening of the heart muscle from deficient coronary supply, and the common occurrence of fibrillation after sudden coronary obstruction; the effects on the brain in the form of giddiness, faintness, or loss of consciousness; and the primarily exciting and secondarily depressing influences exercised powerfully on the medulla (respiratory, vasomotor, and cardio-inhibitory centres, etc.) and on the spinal centres from sufficiently extensive or sudden acute lack of blood supply; also the derangement or stoppage of kidney function from similar interference.

Various observations are on record dealing with the functional behaviour of excised organs and muscles artificially perfused with blood or in the exsanguine condition, and also observations on the effects of artificial interference with the blood supply of organs and muscles *in situ* in animal experiments. Under such conditions there is of course no information obtainable as to sensory phenomena attendant on altered blood supply in the conditions of rest and activity.

The present inquiry deals with the behaviour of human muscles temporarily deprived of their blood supply while their normal innervation remains intact; the sensory phenomena recognizable in the states of rest and activity are examined and brought into relation with other functional conditions, such as changes in contractile power, etc.

#### Methods of Experiment.

The forearm was investigated (a) while the normal circulation was going on, and (b) when the blood supply was stopped, the limb either retaining its blood in a stationary condition or being rendered exsanguine before the circulation was arrested—that is, the "congested arm" and the "ischaemic" arm were examined with arrested circulation. The circulation was stopped by a blood pressure armlet applied to the upper arm, which was rapidly pumped up to a constricting pressure much above what was necessary to produce arterial obliteration in the particular individual examined—that is, an armlet pressure largely exceeding the systolic pressure. When this was done in the usual way, as for the measurement of systolic blood pressure, a "congested arm" was obtained containing a large amount of stationary blood shut off from the general circulation, the veins becoming prominent and tense. To obtain the bloodless or ischaemic arm an elastic bandage was first applied to the hand and arm, and removed after the armlet had been pumped up as described.

In the congested arm the sensory phenomena are naturally complex, being partly attributable to conditions attendant on the arrest of the circulation as influencing the muscles, etc., and partly to the discomfort caused by the venous turgescence. To avoid the latter complication the method of the ischaemic arm is employed; the sensations induced by muscular activity in presence of acute want of blood can then be examined.

Under these conditions muscular action was tested in various ways. Graphic records of the flexor muscle of the

middle finger were made by means of a Mosso's ergograph, the voluntary flexion movements being made in regular series—one in one second or in two seconds, etc.—timed by a metronome, while the weight lifted at each contraction varied in different experiments from 1 to 3 kg. The behaviour of the muscle in different conditions, the amounts of mechanical work done as measured in kilogram-metres, the development of fatigue, etc., were graphically recorded, while the sensations associated with different phases were noted. The results as regards fatigue, etc., will be described elsewhere, the present communication having to do with the sensory phenomena.

Another method is to use a series of grasping movements with the hand, bringing them to bear on a dynamometer or a dynamograph; this method is in some respects less precise than the preceding.

Another mode of experiment was to use the abductor indicis muscle, working against the resistance of a strong elastic band embracing the fingers; successive abduction movements of the fingers were then made in regular series; only the hand was rendered ischaemic in this case, the armlet being applied to the forearm. The hand was supported on a table with the palmar surface downwards. Graphic records can be obtained by making the movements of the finger inscribe on a moving smoked paper.

#### *Ischaemia of the Resting Arm.*

In observations made by these methods it was found that simple deprivation of blood in the ischaemic limb for periods up to twenty minutes caused no great sensory effects, only coldness in the bloodless part, with an inclination to shift the position of the limb, and a certain amount of discomfort from the continued constriction by the obliterating armlet; the absence of pain is to be noted.

#### *Muscular Action in the Ischaemic Arm.*

Muscular action in the ischaemic limb soon becomes painful, and when carried to the point of "fatigue" is acutely painful. "Fatigue" is indicated by inability to go on executing contraction movements even of greatly reduced range. This index of "fatigue" is convenient for comparing the state of matters in normal and ischaemic muscles, though it does not represent inability of the muscle to do more mechanical work in more favourable circumstances—for example, with less resistance opposing the contraction, a lighter weight to lift, etc. It is a useful index of the stage of enfeeblement of the voluntary contractile power with which the sensory manifestations in muscles under different conditions can be correlated. The actual time necessary to induce fatigue and the number of movements that can be executed prior to this point are of course largely influenced by the weight used; with a sufficiently light weight the movements can be kept up for hours without the occurrence of fatigue in the normal arm while the circulation is intact. Under normal conditions the phenomena of fatigue as shown by ergograph records are well known. The associated sensations as the fatigue point is approached take the form of a sense of increased effort being necessary to raise the weight even for a short distance, an increasing disinclination to go on making the successive efforts, aching or dull pain in the central part of the forearm, etc. We have often found a certain amount of local tenderness to pressure in the fatigued muscles, lasting for some little time after action has been discontinued.

In the ischaemic arm the fatigue point is reached much more rapidly, often in one-half or one-third the time needed in the normal arm, with a proportionate diminution in the number of contractions executed, the more rapid development of extensive weakening at a relatively early stage, etc. Pain develops and by the time the fatigue point is reached becomes severe; further efforts at contraction movements lead to distressingly acute pain and the desire for relief becomes urgent, while there is a strong disinclination to attempt further efforts.

#### *Distribution and Characters of the Pain.*

The pain is felt over the flexor aspect of the forearm and is most intense in the central part of the forearm; it is specially marked from wrist to elbow along the line of the flexor digitorum sublimis. It seems to be centred in the belly of the working muscle with a good deal of spreading,

but there is, as a rule, no referred pain in more distant parts; in one subject pain in the palm of the hand was complained of. The pain goes on increasing progressively while contractile activity is kept up; there is no remission, as may sometimes occur markedly in the normal arm, where, working with a suitable load, decided aching may develop at a comparative early stage, to pass off more or less completely at a later stage.

It is to be noted that the pain, increasing to almost intolerable severity in some of these experiments, arises from exercise of a comparatively small amount of muscular tissue—the limited portion of the flexor muscle engaged in moving a single finger—in presence of an acute lack of blood supply, involving urgent want of oxygen (anoxaemia) and its consequences, with excessive accumulation of metabolic products, acids, and other bodies. The pain is no doubt protective in character, tending to limitation of effort and shielding the muscle from being spurred on to further and injurious activity. Discontinuance of further effort for short periods does not remove the pain, but it is almost immediately relieved—in a few seconds—by readmission of blood into the limb by removal of the obliterating pressure of the armlet. Contractile energy, on the other hand, recovers gradually and slowly; it takes some time to be fully re-established, and even then is apt to fail more readily than before on repetition of the experiment. It is evident that the pain and the depression of contraction force do not run parallel in the ischaemic arm.

#### *Relation of Pain to Weakening of Contraction Force.*

The conclusion just stated is supported by the fact that in the ischaemic arm the development of pain in the course of a successive series of contractions is much greater in proportion to the weakening of contraction force than in the arm with intact circulation; with an equally extensive cutting down of the energy of movement in the two types of arm, as shown by the ergograph tracings, there was sharp pain in the ischaemic arm at a stage when there was only a tired feeling with some aching in the normal arm; pain and weakening of contractile force were differently related to one another in the two cases.

It may be noted that in the normal arm slight aching or local tenderness may last for some little time after the exercise of the flexor muscle (as recorded by the ergograph) has been discontinued, while in the ischaemic arm the sharp pain disappears quickly on re-establishment of the circulation. There is reason to believe that in fatigue following severe muscular exertion under normal conditions (for example, football, etc.) the muscular aching and tenderness, felt for a considerable length of time afterwards, especially in individuals out of training, are dependent on a mechanism of production that is not identical with that of the pain caused by working an ischaemic muscle.

The production of severe pain from a small amount of skeletal muscle working with its blood supply cut off recalls the agonizing pain excited by excessive contraction of a small amount of unstriated muscle in a bit of bile duct in gall-stone colic, or of ureter in renal colic, etc. Of course it does not follow that the mechanism of pain production is similar in the two kinds of muscle—the unstriated and the striated.

#### *Observations on the Abductor Indicis Muscle.*

Experiments with the abductor indicis muscle gave results essentially similar to those described above. For example, in an experiment when a certain strength of elastic band was used to resist the abduction movement, a series of about 240 movements could be carried out in the normal state at the rate of one per second before the "fatigue" point was reached—that is, the point where any abduction movement failed to occur against the resistance of the band; this was attended by only slight discomfort and aching—where the latter was present at all. In the ischaemic hand the fatigue point was reached at about one hundred contractions—that is, in less than two minutes, as compared with four minutes in the normal state; this was attended by pain, which spread more or less over the dorsum of the hand, though most sharply felt in the working muscle. Stoppage of the efforts at abduction for a minute did not lead to removal of the pain, but the latter was promptly relieved by re-establishment of the circulation; contractile power recovered much more slowly, and was more easily fatigued subsequently. Some minutes later

the hand was again rendered ischaemic, and kept in that condition with quiescent muscles for ten minutes; the hand became cold, but there was no pain, simple ischaemia having, as described above, no appreciable effect in this respect. Abduction movements of the index finger were then performed as before; there was painful fatigue after about sixty-five movements; the pain was removed as before by readmission of the blood. The usual well-known flushing occurred after the period of ischaemia; sensations of tingling gradually developed somewhat later.

#### *Effects of Continuous Muscular Tension.*

Experiments were also performed with the middle finger flexor muscle kept voluntarily contracted to sustain the ergograph weight at a certain level instead of making a series of consecutive lifting efforts as already described; graphic records of the behaviour of the muscle were made. Continuous motor effect failed to preserve the initial level beyond a certain time, which varied according to the weight employed, etc.; then came a general progressive decline, varied by minor irregularities in the slope of the tracing, until after a time the weight sank back to the resting position. This "fatigue" is attended by comparatively little subjective disturbance, even in the ischaemic arm. There was disinclination to keep up the tension of the muscle, which seems to need more and more voluntary effort, with some discomfort and aching—the latter felt chiefly in the upper arm and the finger—probably attributable not to the muscle itself but to the mechanical conditions connected with the fixed position of the limb and pressure on the skin of the finger by the loop at the end of the cord which supports the weight. There is evidently a notable difference as regards pain production between an alternately contracting and relaxing muscle doing mechanical work and the condition of sustained tension necessary to maintain the weight at certain levels. Similar results were obtained with the abductor indicis.

#### *Relation to Pains of Angina Pectoris, Intermittent Claudication, etc.*

It need hardly be pointed out that the foregoing observations have a close bearing on the problems associated with the production of the pain of angina pectoris, showing as they do how readily acute pain can be excited in skeletal muscle working with lack of blood supply, the pain developing while the contractile power, though to some extent weakened, is still sufficient to execute movements of considerable range and energy—that is, long before complete fatigue.

There is every reason to believe that processes of the same nature, with a similar production of pain of varying grades of severity, up to the agonizing suffering of fully developed angina, occur in cardiac muscle compelled to work with a blood supply that is inadequate—absolutely or relatively to the amount of work which the arm has to perform. Sir James Mackenzie has emphasized the conception of anginal pain as an expression of exhaustion of the cardiac muscle, commonly associated with a defective coronary blood supply and a susceptible nervous system. He has laid stress on the production of the symptoms of heart failure—pain, breathlessness, giddiness, faintness—as expressions of impaired functions of organs which fail to receive a blood supply adequate to the needs of their normal activities in consequence of a defective output of blood from the heart, the latter itself suffering from insufficient blood supply to its muscular walls; heart failure is thus recognized, not by direct examination of the organ itself, but by the functional effects of diminished blood supply to various organs.

It may be added that the results of the present experiments have an obvious application to the phenomena of the condition called "intermittent claudication," as seen in the legs of men and horses, in which muscular exertion is interrupted by attacks of pain, loss of power, coldness of the limbs, etc. These symptoms can be definitely explained: in consequence of blocking of the main artery, or disease or spasm of the vascular walls, the blood stream has been reduced to such an extent that, while it may suffice to supply the muscles in the resting state, it is quite inadequate for their greater requirements during activity—the results (pain, etc.) of the defective blood supply are of the same nature and mechanism of production as those demonstrable in the ischaemic arm of the healthy subject.

## THE CLINICAL, PATHOLOGICAL, AND RADIOLOGICAL ASPECTS OF INFECTION OF THE TEETH AND GUMS.\*

BY

SIR WILLIAM WILLCOX, K.C.I.E., C.B., C.M.G.,  
M.D., F.R.C.P.

PHYSICIAN TO ST MARY'S HOSPITAL.

### *Historical.*

Septic absorption from the teeth and gums must date from the earliest period of man's history, for the examination of ancient skulls shows that dental sepsis has ever been present. The clinical symptoms resulting from infection of the teeth and gums must have afflicted the human race during its whole existence, and it is very remarkable that the causation of these symptoms escaped recognition for so long a period. The recognition of the clinical symptoms resulting from oral sepsis is quite modern.

Disease of the teeth and gums was described by H. A. Fauchard in 1740, and from that date much has been written on the subject. In 1875 John T. Riggs gave a full description of the disease in an address read before the American Academy of Dental Surgery on "Suppurative inflammation of the gums and absorption of the gums and alveolar process," and the disease "pyorrhoea alveolaris" is often called "Riggs's disease."

The next advance in knowledge resulted from the development of the application to the investigating of the cause of dental sepsis. Galippe and P. Labadie, able pioneer work in this respect from 1884 to 1894. The work of Pasteur and Lord Lister on the great influence of bacterial infection in the causation of disease prepared the way for the recognition of the far-reaching effects of the toxic absorption resulting from the organisms found to be associated with dental infections.

Dr. William Hunter, a distinguished Fellow of this Society, was the pioneer amongst physicians in recognizing "the relation of dental diseases to general diseases," and he read an important paper bearing this title before the Odontological Society of Great Britain in 1900. It is not too much to say that the appreciation to-day of dental sepsis as one of the commonest and most important causes of general diseases is very largely due to the unceasing and untiring work of Hunter in this department of medicine.

### *The Bacteria Causing Infection of the Teeth and Gums.*

Professor Miller of Berlin in 1900 carried out a series of brilliant researches on the bacteria found in connexion with dental infections. He found no less than twenty different bacteria in twelve cases of pyorrhoea; amongst them were streptococci, staphylococci, bacilli of various kinds, and leptothrix. Recently, J. McIntosh, Warwick James, and P. Lazarus-Barlow have isolated a bacillus which they believe to be the cause of dental caries and have named *Bacillus acidophilus odontolyticus*.

In this discussion we are mainly concerned with the organisms occurring in dental infections, the absorption of which, or their toxins, gives rise to general disease. There seems to be no doubt that it is the streptococcus infections which are almost entirely responsible. The streptococci found in mouth infections are usually classified into three groups, from their behaviour when grown on media containing blood.

1. *The Haemolytic group* cause severe toxæmia, and are found in the anaemias resulting from dental sepsis.

2. *The Viridans group* includes those streptococci which are associated with rheumatic affections. *Streptococcus salivarius* and *S. faecalis* belong to this group. They are both toxic, producing general toxæmic symptoms, and may give rise to arthritis, fibrositis, and other rheumatic affections. Arthritis and cardiac lesions have followed the inoculation of rabbits with the living organism in either case. Each of them has been found in malignant endocarditis.

3. *The indifferent group of Streptococci* are not toxic to guinea-pigs, and their association with rheumatic conditions is doubtful.

4. *Gram-negative cocci* are found associated with dental infections, but they are not usually toxic, and some of these types have probably been described as staphylococci in earlier writings.

\* Paper read to open the discussion held at the Medical Society London, December 11th, 1922.

5. *Staphylococci* are not usually found in dental infections, but often in the post-nasal space.

In the infections of the teeth and gums the same streptococcus is not necessarily found in different cases, nor can the local disease be constantly transmitted from an infected patient by inoculation of the healthy gums of another person; so that Koch's postulates of a specific infection are not satisfied. The infecting organisms are variable and the infection may be mixed, so that the problem of dental sepsis is a complicated one.

*Evidence for the Conclusion that the Teeth and Gums are the Source of Infection.*

It must not be hastily assumed because a patient is suffering from symptoms such as arthritis, fibrositis, anaemia, or some affection which is commonly associated with dental sepsis, that the teeth are the cause of the illness. Every case must be approached with an open mind and no preformed opinion.

There are many other foci of infection which may produce diseases identical with those resulting from dental sepsis; in other words, a streptococcal toxæmia may be due to a great many causes other than dental. Thus the tonsils, the nasopharynx, the intestine, and the urogenital tract may all be foci of infection for pathogenic streptococci or other organisms. Careful examination should always be made to determine if these other foci of infection may safely be excluded.

The practice of extraction of apparently healthy teeth merely because a patient is suffering from a disease which is often due to a dental infection cannot be too strongly condemned. There should always be strong evidence that the teeth are primarily and directly responsible for the disease in other organs before their extraction is justifiable.

*The Signs of Unhealthy Conditions of the Teeth and Gums.*

The presence of gingivitis is shown by an unhealthy spongy condition of the gums, which bleed readily and have a congested free margin. Often congested hyperplastic projections occur between the teeth. These are particularly well marked in scorbutic conditions and have been described as "buds." Tartar and dirty collections may be present between the free surface of the gums and teeth. Pressure on the gums may cause pus to ooze up from between the gums and teeth if pyorrhoea is present. Local swellings of the gums due to periosteal abscess may occur. The teeth themselves may show marked caries with gingivitis around them. An important clinical symptom often present is a sweet sickly smell of the breath.

In a large number of patients who habitually clean their teeth carefully little or no evidence of a dental infection can be found from an external examination; this point cannot be too strongly emphasized. On many occasions I have seen teeth and gums, apparently perfectly healthy, in which radiographic examination disclosed dangerous peri-apical necrotic lesions. Sir Frank Colyer truly says, in his book on *Chronic General Periodontitis*:

"It is not safe to judge the extent of the disease from clinical appearances only, and it is necessary to call in the aid of skiagraphy in order to ascertain how far bone destruction has proceeded."

The gums may appear healthy, and yet there may be an extensive disease of the alveolar process around the roots of the teeth, and considerable bone destruction, the involved area being heavily infected with pathogenic streptococci. The grave clinical effects resulting from infected bone are well known, and from observation of a large number of cases which have been carefully investigated by bacteriological and radiological methods I am strongly of opinion that the general clinical effects produced by dental infections are accounted for by the extent and nature of the disease of the bone in the neighbourhood of the teeth, rather than in the gums or teeth themselves, though these latter are the primary causes of the bone disease.

It cannot be insisted upon too strongly that in every case of illness in which the teeth may be primarily responsible—even if external appearances of the teeth and gums are healthy—a radiographic examination should be made to ensure that the alveolar process around the teeth is also healthy.

*Radiographic Evidence.*

Careful photographs of the teeth and surrounding jaw, taken so that two or three teeth only are included in each plate, will show in detail the exact condition of the roots of the teeth and surrounding bone.

The periodontal membrane of a tooth may be swollen, and the alveolus may show superficial erosion, such as occurs with advanced age, but the most important evidence of all is the presence of necrosis of bone in a more or less spherical area around the apex of the tooth.

These apical lesions are commonly called "apical dental abscesses." The term is a bad one, because there is no pus present, and, most important of all, they give rise to no pain. The term "apical granulomata" has been used; this also is bad, because the microscopical appearances are not those of a granuloma.

When a tooth is extracted with an apical dental lesion, a mass of solid gelatinous substance is found adherent to the apex. This contains pathogenic streptococci and necrotic substance with very few leucocytes. The term "peri-apical bone necrosis" would accurately describe the condition actually present.

In my opinion the "peri-apical bone necroses"—the so-called "apical dental abscesses"—are the most serious lesions found in connexion with dental sepsis, and it is these which give rise to the gravest general disease resulting therefrom. It is probable that from these lesions there is a constant flow into the blood stream of either virulent streptococci or their toxins, and the anatomical position of the lesions prevents an adequate supply of leucocytes and bactericidal body fluids to the part.

An interesting example of the deadly effect of even a small peri-apical bone lesion may be cited here.

CASE 1.

In 1919 a patient, aged 46, had been under my care for some months, suffering from the effects of long residence in the tropics. He was in fairly good health and then developed an irregular pyrexia. No evidence of malaria was found and the pyrexia did not respond to quinine. A systolic murmur was present in the apical cardiac area, which was of old standing. A blood culture made by Dr. J. Matthews showed a streptococcal infection. Although the teeth had been pronounced perfectly healthy by an experienced dental surgeon an x-ray examination was made, and this revealed the presence of a "peri-apical bone necrosis" round one of the lower central incisor teeth. Extraction of the affected tooth showed a marked infection with streptococci, identical in characters with those found in blood culture. The patient developed additional cardiac valvular lesions and was seen in consultation with me by Sir William Hale-White. The condition was obviously one of infective endocarditis, and this subsequently terminated fatally.

If lesions of this kind are present, the maintenance of health is obviously impossible; some serious general disease is bound to result if it has not already appeared. In my opinion if a lesion of this kind be present no compromise is permissible—the affected tooth must be extracted.

Gardner of America has asserted that extraction of the tooth is not a sufficient safeguard and advises a preliminary trephining of the alveolar process over the peri-apical lesion. The diseased area is then curetted, the tooth extracted, and the infected area sterilized by the application of a suitable antiseptic. In this country the simple extraction of the affected tooth is, I think, considered adequate, and trephining and curettage are not thought necessary.

Where "peri-apical bone necroses" are present the affected tooth is usually dead, and this is an important indication. Attention must here be called to the very common occurrence of this dangerous lesion in connexion with crowned teeth. So common is this occurrence in my experience that I have no hesitation in condemning the procedure of crowning teeth.

*Does the Simple Erosion of the Surface of the Alveolar Process around Teeth Call for Extraction?*

Each case must be judged on its merits. If there are no obvious symptoms of streptococcal toxæmia, I should say that the answer to this question is No. The presence of gingivitis without bone disease around the teeth should be amenable to treatment and does not necessarily call for extraction.

The presence of pyorrhoea alveolaris does not of itself demand extraction of the teeth. This should only be decided upon after considering the radiographic evidence in conjunction with the local symptoms of pyorrhoea. Also the gravity of the constitutional toxic symptoms resulting from the pyorrhoea will be an important factor. It must be remembered that sometimes pyorrhoea alveolaris may be a secondary symptom of some primary disease, such as dysentery, colitis, scurvy, etc., and if the general disease is cured the cure of the pyorrhoea may follow naturally.

The general factors which influence the effects of dental sepsis are:

1. *The Virulence of the Organism.*—Just as in other pathological infections—diphtheria, for example—a small lesion, if the organism is virulent, may produce very severe effects, or an extensive local dental lesion may give rise to little constitutional disturbance.

2. *The amount of toxins absorbed into the circulation* is an important factor. Everyone who is familiar with hospital out-patient practice has been impressed by the appalling dental sepsis observable by the naked eye in patients with no constitutional symptoms therefrom. The reason must be that there is free discharge of the toxins produced. On the other hand, an invisible deep-seated lesion with healthy gums may be associated with the most severe constitutional effects. The "time factor" is important. If there is only slow absorption the toxic effects will be slighter than with rapid absorption. The whole question is one of dosage with toxin.

3. *The Resistance of the Patient.*—This is a most important factor. Some patients, from constant absorption of toxins, become extremely sensitive, and a condition of anaphylaxis results. The recent work of Sir Almroth Wright on septicaemia is most interesting in this respect, since he has shown that in certain conditions of septicaemia the patient is incapable of developing bactericidal substances. Julius A. Toren of Chicago showed (1921) that in certain cases of dental infection and gingivitis a leucopenia occurred, and he regarded this as an anaphylactic phenomenon and a signal of danger. He concluded that in this condition extraction of many teeth was dangerous, and advised removal of not more than one at a time. This observation has a very important practical bearing.

#### *Secondary Intestinal Infection.*

Where dental sepsis is present and it has given rise to general disease, examination of the stool or intestinal washings shows in practically every case a marked preponderance of streptococci similar to those present in the dental lesion. This is an important factor in the consideration of the general effects produced by dental sepsis, for in most of these cases there is a secondary intestinal infection which may of itself cause similar general disease. This explains why in advanced cases of arthritis the disease may progress when the primary dental focus of infection has been eradicated.

#### *The General Diseases caused by Infection of the Teeth and Gums.*

Infection of the teeth and gums by reason of the streptococcal infection arising therefrom is undoubtedly one of the greatest sources of disease of adult life.

*Acute streptococcal septicaemia and septic-pyæmia* have not infrequently arisen from dental sepsis. The risk of this dangerous complication must always be borne in mind in connexion with the extraction of infected teeth in patients whose resistance to streptococcal infection is low. As already mentioned, a leucopenia is a danger signal.

*Toxaemia* is commonly associated with dental sepsis. It may be chronic, subacute, or acute. Chronic toxaemia is present in a great many of these cases, and in all where some general disease has resulted from the primary dental infection. There is a feeling of malaise and general ill health, a tendency to exhaustion on slight exertion, a pale and muddy complexion is common, and often some general pains in the hands and feet indicate an irritation of the peripheral nerves; frequently some symptoms of fibrositis or threatening arthritis occur. Insomnia, headache, and dyspeptic symptoms are common. In such cases a careful radiographic examination of the teeth should always be made.

Subacute toxaemia may give rise to intermittent pyrexia, with general constitutional symptoms of ill health, extending over months and years.

#### CASE II.

F., aged 32, recently seen by me, had had an irregular pyrexia for three years, the temperature in the evening commonly being 100° or 101°, and marked constitutional symptoms of ill health were present. Extensive bacteriological investigations had been carried out, with negative result, beyond the finding of a streptococcal infection in the stools. Vaccine treatment had been of no avail. An x-ray examination of the teeth showed two extensive peri-apical necroses, although to external appearances the gums and teeth were healthy and no toothache had occurred.

Extraction of the infected teeth by Sir Frank Colver resulted in the complete disappearance of the pyrexia and restoration to good health.

In some cases pyrexia and general symptoms of ill health are followed by profound *acute toxaemia*, and a condition of stupor, delirium, and coma result.

#### CASE III.

M., aged 57, had had malaise and irregular pyrexia due to septic teeth. In consequence of this six teeth were extracted on July 24th, 1921. The operation was followed by a condition of profound toxaemia, the patient being in a "typhoid state" with pyrexia, stupor, and low delirium; there was slight splenic enlargement and a macular rash.

All tests for enteric or typhus infections were negative, and it was clear that a severe streptococcal toxaemia was present.

On August 8th the patient was in a lethargic stuporose state, with mild pyrexia, and the condition was very grave.

Several unhealthy crowned teeth were still present, and it was decided to remove one of these each day. The removal of the remaining infected teeth was followed by disappearance of the toxaemic condition, and the patient made a complete recovery. Dr. Geoffrey Evans made a most careful study of this case, and we were both of opinion that the removal of the remaining infected teeth, even though the condition was most grave, held out the only hope of recovery.

#### *Local Infective Conditions Resulting from Dental Infections.*

Such conditions as stomatitis, tonsillitis, naso-pharyngeal infections, infections of the maxillary antra, cervical adenitis, and Ludwig's angina have been observed.

#### *Blood Conditions.*

A secondary anaemia, mild or severe in type, is a common result of dental sepsis. The more severe types of anaemia are associated with streptococci of haemolytic type. In many cases of pernicious anaemia a severe dental infection with haemolytic streptococci is present. Hunter does not regard dental sepsis alone as a sufficient cause of pernicious anaemia, but rather as a predisposing cause to which an additional factor is added.

*Leucocytosis* is commonly present, and usually the differential count approximates to the normal. It may show variations in different cases, and in the same case at different stages of the disease.

Some acute cases show a marked relative lymphocytosis. This may be a true lymphocytosis, or simply an apparent lymphocytosis, due to a polymorphonuclear leucopenia.

Thus, in one acute case the blood examination on July 22nd, 1922, showed a leucocytosis of 16,600, with 17.5 per cent. of polymorphonuclears and 79.5 per cent. of lymphocytes. On August 3rd the polymorphonuclears were 30 per cent. and the lymphocytes 65.7 per cent. On August 9th the polymorphonuclears were 64.29 per cent. and the lymphocytes 34.28 per cent.

Another similar acute case showed on February 9th, 1921, a normal differential count, and on April 20th the lymphocytes were 52 per cent. and the polymorphonuclears 44 per cent.

An increase of the eosinophilia is uncommon. Two cases, however, have come to my notice.

The first patient (Case 1) gave, on August 24th, 1919, 20 per cent. of eosinophile leucocytes; on September 3rd 12 per cent.; on November 22nd 15.05 per cent., and on January 9th, 1920, 8.17 per cent.

Another patient, who had never resided in the tropics, showed 9 per cent. of eosinophile leucocytes in the differential count.

The presence of leucopenia in some cases has already been alluded to.

#### *Cardio-vascular Complications.*

*Streptococcal infections* of dental origin may cause phlebitis and venous thrombosis, and also arterio-sclerosis, which is not necessarily associated with an increase in the blood pressure. The changes in the arterial wall may give rise to narrowing of the lumen with symptoms of intermittent claudication, or even arterio-thrombosis.

*Cardiac Conditions.*—Tachycardia of toxic origin is often to be observed, and pericarditis, myocarditis, and myocardial degeneration may occur. Endocarditis when present may be of the simple type, such as occurs in acute rheumatism, but not infrequently dental sepsis gives rise to ulcerative endocarditis. Five such cases have been under my care during the past three years, where the origin of the infection appeared to be definitely the teeth.

#### *Respiratory Complications.*

The streptococcal infection may give rise to laryngitis, tracheitis, and bronchitis. Pleurisy and empyema were described by Hunter in 1900 as possible complications. Septic bronchopneumonia is a serious and not uncommon complication, and it may be followed by bronchiectasis, or lung abscess.

At the present time a patient is under my care in St. Mary's Hospital suffering from abscess of the lung the result of very severe dental sepsis. Attention has been called to the adverse influence of dental infections in cases of pulmonary tuberculosis by Dr. R. C. Wingfield.<sup>2</sup> He considers the removal of dental sepsis an essential preliminary in the treatment of pulmonary tuberculosis, and says that in such cases untreated oral sepsis may frequently turn the balance against the patient.

#### *Gastro-intestinal Complications.*

Dental sepsis is one of the commonest causes of gastric and intestinal dyspepsia. Hunter in 1839 laid stress on the frequency of toxic or infective gastritis, and he then expressed the opinion that dental sepsis was the probable cause of some cases of that rare condition "phlegmonous gastritis."

*Gastric and duodenal ulcer* probably result from septic infection, and the trend of opinion at the present time is that dental sepsis is a most important cause. In my experience it is rare to find a case of gastric or duodenal ulcer in which an adequate explanation of the cause cannot be found in the condition of the teeth and gums, and I should say that dental sepsis was much the most important etiological factor. The work of Rosenow in America gives strong support to the view that gastric and duodenal ulcer arise from streptococcal dental infection, and he has produced gastric and duodenal ulcer in animals from inoculation with cultures of human dental streptococci.

*Appendicitis* is, in many instances, due to a streptococcal infection, and several cases have recently been under my care in which the primary infection appeared undoubtedly to arise from the teeth.

*Enteritis*, with symptoms exactly like paratyphoid fever, including enlargement of the spleen and similar pyrexia, may undoubtedly result from streptococcal dental infections. The differential diagnosis can only be made by complete bacteriological investigations, and by the recognition of the dental disease for which often radiological examination is necessary. Three cases of this kind have been under my care.

*Colitis*, simple and ulcerative, is frequently due to a streptococcal infection, and in many of these cases the primary focus is undoubtedly connected with the teeth. Peri-apical dental necroses will often be found in intractable cases of colitis. Dr. N. Mutch<sup>3</sup> has called attention to the frequency (84 per cent.) of pathogenic streptococci in the colon in an analysis of 200 cases of arthritis. In 52 per cent. of these cases he concluded that the primary focus was a dental infection.

#### *Renal Complications.*

Nephritis has been described by many writers as sometimes resulting from dental sepsis.

#### *Liver Complications.*

Toxic conditions of the liver are well known to result from streptococcal infections, and frequently slight jaundice and evidences of hepatic disturbance are observed in cases of dental infection. There can be no doubt that hepatic efficiency is often impaired as the result of the toxæmia from dental sepsis.

#### *Skin Complications.*

Rashes of an erythematous, urticarial, papular, and eczematous type have been observed. Purpuric rashes may occur, especially where the streptococci are of the haemolytic type.

#### *Eye Complications.*

Conjunctivitis, iritis, irido-cyclitis, episcleritis, retrobulbar neuritis, have all been described as resulting from dental infections. Undoubtedly vascular lesions, such as thrombosis of the central artery or vein of the retina, may be so caused. Of special interest is retinitis. Dr. Batty Shaw has recently called attention to the great importance of the toxic factor in this condition, and undoubtedly dental sepsis is not infrequently the cause.

#### *Nervous Diseases.*

The toxæmia from dental infections may give rise to cerebral conditions such as abnormal mental states, melancholia, etc., and it is possible that inflammatory conditions, such as meningitis, may be so caused.

Spinal cord diseases, such as combined sclerosis with its associated anaemia, disseminated sclerosis, etc., are often due to toxic causes, and dental sepsis must be included amongst these.

Peripheral neuritis may occur from the streptococcal toxæmia of dental origin, and the sensory symptoms, tingling, and numbness of the hands and feet are of common occurrence. Local neuritis, such as sciatica, brachial neuritis, etc., is a common result of dental sepsis, but these are better included under the fibrositis group, because the cause is rather a perineuritis than a primary involvement of the nerve fibres.

#### *Rheumatic Conditions.*

In a paper published in the *BRITISH MEDICAL JOURNAL* (June 4th, 1921) I called attention to the great importance of infection of the teeth and gums in the causation of rheumatic conditions such as fibrositis and infective arthritis.

*Fibrositis*.—The streptococcal infections so arising may give rise to the various forms of fibrositis—namely, panniculitis, inflammatory conditions of fasciae, and aponeuroses—as occurs in lumbago and myalgic conditions; inflammations of tendons and ligaments, such as stiff neck, tender heels due to involvement of the plantar ligaments, Dupuytren's contractions of the palmar fascia; inflammations of tendon sheaths, arterio-synovitis; bursitis; Heberden's nodes; finger pads; fibrous nodules in subcutaneous tissue; local perineuritis and neuritis, as in sciatica and brachial neuritis. Fibrositis in some of its forms is the commonest occurrence in cases of dental and gum infections.

*Non-specific infective arthritis*, which includes the forms known as rheumatoid arthritis, arthritis deformans, osteoarthritis, and chronic villous arthritis, is generally due to a streptococcal infection. Dr. Beddard, in a paper before this Society in October, 1918, expressed the opinion that 90 per cent. of these cases were due to infection arising from the teeth, and my personal experience agrees with this view.

It is well known that in cases of non-specific infective arthritis numerous bacteriological examinations have shown that no living organisms are to be found in the joints. It is probable that the streptococcal toxins give rise to the inflammatory conditions. The recent work of Dr. W. E. Gye, and Dr. E. H. Kettle has shown that marked proliferative changes can occur in organs such as the spleen, through the action of colloidal silica, without the presence of living micro-organisms.

*Acute rheumatism* is not commonly caused by dental infections, but several cases have been described. The organism found by Poynton and Paine in numerous cases of acute rheumatism closely resembles the *Streptococcus salivarius* and *S. faecalis* found in dental infections.

#### *Gout.*

In some cases of gout dental sepsis is important, and should be removed, as far as possible, in every gouty patient. Dr. Llewellyn has expressed the opinion that gout is the result of a toxic idiopathy to certain toxic protein substances. Undoubtedly the streptococcal toxins of dental origin are in not a few cases the important causative factor.

#### *Diabetes.*

Streptococcal and other toxins may cause a toxic glycosuria, probably by impairment of the endocrine function of the pancreas. Dental sepsis is undoubtedly a factor in the causation of glycosuria in some cases, and it should always be removed in cases of diabetes. A rise in the carbohydrate tolerance has often been observed by me after the removal of dental sepsis in early cases of diabetes.

#### *Scurvy.*

This disease, due to vitamin deficiency, shows marked dental sepsis on its earliest appearance. During the war over 20,000 cases of scurvy occurred amongst Indian troops in Mesopotamia, many of which I personally examined, and in almost all very marked infection of the teeth and gums was present. The result of careful observation showed that if pre-existing dental sepsis was present in a marked degree, then such patients were very predisposed to develop scurvy.

#### *TREATMENT.*

The treatment of infections of the teeth and gums, and the diseases arising therefrom, does not come within the scope of this discussion. The most important general principles in the treatment of such infections have, however, been indicated, namely:

First, remove the focus of infection, either by extraction of teeth, or suitable treatment.

Secondly, it must be remembered that intestinal infections very frequently result from dental infection, and these may

qure treatment by such measures as Plombières colon irrigations, or an autogenous vaccine prepared from the streptococci found in the teeth and intestine.

### Prophylaxis.

The early recognition of dental sepsis and its appropriate treatment would be one of the most important factors in greatly improving the health of the nation.

## REMARKS ON THE VALUE OF BUTYN AS A LOCAL ANAESTHETIC.\*

BY

W. M. BEAUMONT,

CONSULTING OPHTHALMIC SURGEON, S.W. REGION,  
MINISTRY OF PENSIONS.

For some years the experts connected with the Abbott laboratories of Chicago experimented assiduously to find a synthetic substitute for cocaine, and in 1918, with the collaboration of Professors Roger Adams and Oliver Kamm of the University of Illinois, butyn was discovered; in their opinion it fulfils all the requirements they had in view. The next step was to refer butyn to a committee of the Section of Ophthalmology of the American Medical Association under the chairmanship of Dr. Albert Bulson, jun., of Indiana, and after prolonged clinical investigation a report was published early in 1922. The conclusions are summarized as follows:

1. Butyn is more powerful than cocaine, a smaller quantity being required.
2. It acts more quickly than cocaine.
3. Its action is more prolonged than that of cocaine.
4. Butyn in the quantity required is less toxic than cocaine.
5. It produces no drying effect on tissues.
6. It produces no change in the size of the pupil.
7. It has no ischaemic effect and therefore causes no shrinking of tissues.
8. It can be boiled without impairing its anaesthetic efficiency.

Unlike cocaine, it does not deteriorate quickly by keeping—an advantage to those practitioners who wish to have supply ready in case of emergency. Still more important, it has no attractions for the drug taker.

Professor Adams in a letter tells me that his first experiments on toxicity were disappointing because he found that with mice butyn was two or three times as toxic as cocaine. But, on the other hand, its anaesthetic power was also two or three times as great as cocaine. Further experiments showed him that the comparative degree of toxicity varied with the size of the animal. For instance, with guinea-pigs the two substances are about equally toxic. In cats butyn is about 5 per cent. less toxic, and in dogs from 25 to 30 per cent. less toxic than cocaine. In monkeys the toxicity of butyn is probably as low as 50 per cent. compared with cocaine; but these latter experiments are not yet completed. Professor Adams considers that it may be concluded that in man it is still less toxic. This view is supported by the fact that no toxic symptoms have occurred in America although butyn has been used in many cases. The low toxicity of butyn was confirmed by the committee of the Section of Ophthalmology of the American Medical Association.<sup>2</sup> In the opinion of the manufacturers butyn is probably considerably less than half as toxic as cocaine.

### Tests.

Dissolve 1 gram of butyn in 10 c.c.m. of water. Separate portions of the solution yield a white precipitate with potassium mercuric iodide solution; a brown precipitate with iodine solution; a brown precipitate with gold chloride solution; and a yellow precipitate with picric acid solution. A portion to which barium chloride solution is added gives a white precipitate (distinction from cocaine).

Dissolve about 0.1 gram of butyn in about 5 c.c.m. of water, add drops of dilute hydrochloric acid and 2 drops of sodium nitrate solution (10 per cent.) and mix with a solution of 0.2 gram of beta-naphthol in 10 c.c.m. of sodium hydroxide solution (10 per cent.). A scarlet-red precipitate is formed (distinction from holocaine, which gives a white precipitate).

\* Read at a meeting of the Bath and Bristol Branch of the British Medical Association, November 29th, 1922.

To a solution of about 0.1 gram of butyn in 5 c.c.m. of water add 3 drops of diluted sulphuric acid and mix with 5 drops of potassium permanganate solution. The violet colour of the latter disappears immediately (distinction from cocaine).

Dissolve about 0.1 gram of butyn in 1 c.c.m. of sulphuric acid. The solution is colourless (organic impurities).

Dissolve 0.1 gram of the salt in 10 c.c.m. of water and saturate with hydrogen sulphide. No coloration or precipitation occurs (salts of heavy metals).

Incinerate about 0.5 gram of butyn accurately weighed. There is not more than 0.2 per cent. residue.<sup>3</sup>

Early in 1922 I resolved to try butyn, but the impossibility of getting it in England caused some delay, and it was necessary to send to Chicago. Unlike some German substitutes, butyn, not being a derivative of cocaine, can be freely prescribed without restriction.

### In Eye Work.

In ophthalmology butyn has been extensively used in the United States. Dr. H. S. Gradle, from an experience of more than 2,000 cases, finds it superior to cocaine and holocaine in eye surgery.<sup>4</sup>

My own experience is confined to about 60 cases, including operations for the extraction of cataract, discission, iridectomy, removal of foreign bodies, and skin operations on the lids by infiltration. For operative work on the eye a 2 per cent. solution is used, but for profounder anaesthesia 4 or 5 per cent. Four applications should be made at intervals of two minutes. If a bloodless field is required, a drop or two of adrenaline solution (1 in 1,000) may be instilled after the last drop of butyn. The eye is then ready for operation. For operations on the skin of the lids 10 drops or more of a 0.5 per cent. solution may be injected subcutaneously with a hypodermic needle.

For all operative work on the eye, in my experience, butyn is most satisfactory, the anaesthesia being more profound and prolonged than when cocaine is used, and there are no after-effects. I sum up my present position with regard to butyn by saying that neither in the consulting room nor in the operating theatre have I found it necessary to resort to cocaine during the last nine months.

### Butyn in Ear, Nose, and Throat Work.

Some 200 operations have been done, including septum resection, tonsillectomy, adenectomy, opening accessory sinuses, etc. It can be used in a 2 per cent. solution and applied topically. It acts efficiently and is superior to a 5 per cent. solution of cocaine. For profounder anaesthesia for major operations on the throat and nose, 5 per cent. may be used, and adrenaline can be added for all intranasal operations. Dr. Bulson of Indiana reports that still stronger solutions can be used in throat operations.<sup>5</sup> For intranasal work he employs a 5 per cent. solution of butyn, with epinephrin, swabbed over the operative field and beyond, if possible.

"Within two or three minutes following the first application, flattened pledgets of cotton soaked with the solution, but from which the surplus has been squeezed out, are applied over the operative field and when possible over the source of the sensory nerve supply. These pledgets are removed after the end of five to eight minutes. Five minutes later the operation may be commenced with the assurance that in practically all cases the patient will suffer no pain or even discomfort."

I can find no record of butyn having been used as a spray. Nevertheless there seems to be no contraindication.

### Butyn in Dentistry.

In dentistry butyn is notably satisfactory. There are none of the after-symptoms which sometimes occur with other local anaesthetics. Ten drops or more of a 1.2 per cent. solution are injected on opposite sides of the tooth to be extracted, with or without adrenaline, and after sixty seconds the tooth is ready to be removed. I quote the following from a report issued by the Abbott laboratories.

"In March, 1921, the first (dental) extractions under butyn anaesthesia were performed by a Chicago dentist. Following about 100 such cases, quantities of butyn were sent to a considerable number of dental practitioners in all parts of the country. These men used butyn in various concentrations for all types of dental anaesthesia. As their reports began to come in it was apparent that it was producing results of a far more satisfactory nature than had at first been expected. The dentists who were co-operating with us in this research simply had to tell their friends of the unusually fine results they were getting with this new

give the candidate and his guardians a guarantee of some sort of fitness for the work. Most local education authorities have instituted such tests. That they are not always satisfactory is indicated by reports of some school medical officers. There is also a necessity for some measure of uniformity in the tests throughout the country, for trained teachers are in a sense current coin and legal tender to any educational authority. It is in every way good that this should be so, for the more movement there is amongst the teachers the wider their outlook and the better teachers they make. It is therefore lamentable when a teacher trained by one authority is rejected on account of defective eyesight by another authority. The purpose of this paper is to suggest for agreement the limits of defective sight permissible for candidates for scholarships, training college, and teaching posts in council elementary and secondary schools.

Children in elementary schools are examined as a matter of routine thrice—at about the ages of 5, 8, and 14 years. Children suspected of defect are examined at any time. The average age for entry upon a junior county scholarship is 11 years; the holder is transferred to a secondary school for five years. Intermediate scholarships are awarded a year later, and give four years at a secondary school. Senior county scholarships are granted at the age of 16 years and are available at a university for four years. Prospective teachers undergo training at a college between the ages of 17 and 20 years. Thereafter a teacher's life extends to the age of 65 years, when a pension is earned. During service failure of health is met by temporary allowances on a generous scale, and a complete breakdown necessitating retirement is met by a modified pension and a gratuity after ten years' service and a small gratuity after two years' service. Such provision adds to the necessity for care in the selection of candidates.

#### *Defective Vision and Inefficiency.*

In considering what limitation in defect should be made at the several stages of an educational career it is convenient to take the teacher first. If we can arrive at a fair standard of fitness at about the age of 21 years at the entry to the strenuous career of forty-five years' teaching, and a standard that will provide a reasonable prospect of efficient service and limit the risk of early disablement, the main part of our task is done. It will be comparatively easy from that standpoint to adjust a scale fitting junior and senior scholarships and a college course.

The question will at once arise, What evidence is there of inefficient service or disablement due to defective vision? That question is not easy to answer in terms of figures. Such answer of this sort as is possible I gave this year in a paper read before the Ophthalmological Society.<sup>1</sup> That evidence dealt with myopes only. Similar evidence for hypermetropes cannot be presented. Every ophthalmic surgeon sees a fair selection of myopes, because all myopes suffer the disability of being unable to see. We do not get a similar fair selection of hypermetropes; we get only those who fail to see with comfort. So that although it is possible to suggest a definite answer as regards the myopes we can only arrive at an estimate in the case of hypermetropes based upon our general appreciation of the effects of hypermetropia in causing eyestrain in early middle life, from 30 to 35 years, when the rigour of youth and its compensatory powers are beginning to wane. The evidence as regards the myopes is as follows:

A series of histories were gathered of myopes of over 3 D. between the working ages of 20 to 60 years, and classified according as they were engaged in close work all day or in manners of life which did not entail habitual close work. Of the close workers, no less than 53 per cent. came to a time when there was an unmistakable failure of ability to carry on because of serious eyestrain; some changed their occupation to work that did not entail close eye work; most could not do this, and had to "cut canny" for the sake of their eyes. Of myopes of the same types and ages who were not engaged in continuous close work, only 9.4 per cent. experienced a critical failure of capacity owing to eyestrain or disease. If we classify the myopes who were engaged in habitual close eye work according to degrees of myopia we get the following:

Myopia 3 to 5 D. ...	Breakdown 33.7 per cent.
... 5 to 10 D. ...	66.5
... over 10 D. ...	77.4

These figures represent a fair indication that myopia of more than 5 D. presents an undue risk of inefficiency or breakdown for teachers, who must be classified as those who are engaged in habitual close eye work.

#### *Suggested Standards for Teachers.*

**Visual Acuity.**—The vision of each eye separately should equal Snellen's 6/9, with glasses needed to correct an error of refraction within the allowable standards; or with inequality of the eyes, 6/6 in the better eye and 6/18 in the worse, also with glasses. Exceptions may be allowable in amblyopia of one eye or loss of one eye not arising from disease (vide infra).

**Hypermetropia.**—This usually only causes trouble when it exceeds 5 D. With this degree, or more, vision can rarely be brought to the full 6/6 standard with glasses. The subjects of the defect are very liable to headaches and failure of vision in periods of ill health; these concomitant disorders are more frequent in women than in men. Candidates with hypermetropia not exceeding 5 D. may be accepted.

**Hypermetropic Astigmatism.**—When this error is uncomplicated by hypermetropia the error should not exceed 4 D.; higher errors are very troublesome; full vision of 6/6 is rarely obtained with the most suitable glasses. With compound hypermetropic astigmatism the average is found—that is, the sum of the four meridians should be divided by 4; if the quotient does not exceed 5 the candidate may be accepted provided the total astigmatism does not exceed 3 D. in either eye: for example, R. and L. +3.5 D. sphere + 3 D. cylinder, the sum of the four meridians = 20 and the quotient 5, the candidate would be passed. Both hypermetropia and hypermetropic astigmatism are very liable to cause fatigue on close work and in ill health, and the defect becomes increasingly disturbing with years, so the decision regarding any candidate has to be made with this regard.

**Myopia and Myopic Astigmatism.**—The defect has its own special disability in that it is not only liable to cause strain but that it is very likely to increase with work. Also there is the additional liability to degenerative changes in the eye, whether of vitreous lens or of choroid and retina. Simple myopia of 5 D. or myopic astigmatism of 4 D. should be passed. In compound myopic astigmatism the total myopia should be calculated in the same manner as the hypermetropia; the sum of the four meridians should be divided by 4, and if the quotient does not exceed 5, and the total astigmatism in either eye does not exceed 3 D., the candidate should be passed. Mixed astigmatism should be classed with myopic astigmatism.

**Odd Eyes.**—When one eye has (a) normal vision with 6/6 vision or better, or (b) the vision of 6/6 with glasses correcting an error of refraction not exceeding plus or minus 3 D. sphere, less importance should be attached to the defect of the other eye, provided there is no sign of disease in that eye: for example, R.—3 D., L.—5 D. sphere with —4 D. cylinder, sum of meridians=20, quotient 5, the candidate may be passed. Amblyopia in one eye due to squint, the deformity of which has been satisfactorily corrected, should not disqualify.

Loss of one eye by reason of accidental injury which in no way affects or is likely to affect the remaining eye should not disqualify for scholastic studies or employment, provided the deformity is satisfactorily masked by an artificial eye. Monocular cases should not be admitted to trade scholarships where there is risk of injury arising out of the work.

**Opacities.**—The presence of opacities in the media of the eyes, or of uveitis, should render the candidate unfit at any age. Cases showing signs of past or present iritis, cyclitis, and most cases of keratitis would, under this rule, be disqualified, but not cases of stretching of the choroid about the optic discs due to the allowable degrees of myopia.

**Colour Vision.**—This should be tested in every case, but deficiency in this respect should not disqualify the candidate except in special circumstances.

**Sex Differences.**—If it be not too great a heresy in these days to distinguish between men and women candidates, I should be inclined to allow men a greater margin of error than women. That high conscientiousness of women, so admirable in the nursery, becomes a source of weakness to the school teacher; women also appear to be more susceptible to the effects of eye defect in causing neurasthenia than do men; further, the more sedentary pursuits of women out of school render their health less robust than the men's and their liability to strain greater.

#### *Standards for Scholars.*

For children, the same limitations should apply as regards visual acuity, hypermetropia, hypermetropic astigmatism, odd eyes, and damaged eyes, as for the teachers. The only difference in the scale will arise in the case of myopia and myopic

standards, such as will do bar as few promising candidates as possible and yet limit future risks. It cannot be too strongly urged that decisions in scholastic cases are decisions for a lifetime, and not merely decisions for the three years or so of military service. It is therefore better in every way to stop a dubious case at the very beginning, when a diversion of interest is easy, rather than to risk the grievous hardship of a stoppage in the future, with the possible wrecking of an established career.

## THE EFFECT OF ANAESTHETICS ON THE LUNGS.

(Preliminary Communication.)

BY

R. J. S. McDOWALL, M.B., D.Sc., M.R.C.P. EDIN.

(In the Department of Physiology, University of Leeds.)

In the issue of this JOURNAL for November 11th, 1922, was published the report of the discussion at the Annual Meeting of the British Medical Association on broncho-pulmonary complications following operations under anaesthesia, and it was a strange coincidence that the succeeding article should be on the effect of anaesthetic vapours on tissues, in which Flemming has collected a very interesting series of experiments which show their detrimental effects on tissues and living organisms in general. In the first article stress was placed on the possible irritant effect of the vapours on the lungs; in the second no special emphasis was laid on the effect on the lung tissue.

It does not seem to be appreciated that the lung tissue may, apart from mere irritation, suffer serious damage as a result of actual contact with the vapour, apart from concentration in the blood.

Until quite recently knowledge of the function of the lung tissue was comparatively small, apart from the fact that the lungs were adapted for the supply of oxygen to the blood. The function of the bronchial muscles has been largely ignored and the physiology of the pulmonary circulation has been avoided, largely because of the experimental difficulty involved in its study and the negative results obtained by several well-known investigators. From book to book it had become quoted that the vasomotor mechanism in the lungs was negligible. Why there should be such an amount of muscular tissue in the lungs remained unexplained.

Much controversy centres round the action of adrenaline on the pulmonary circulation, as it is accepted that generally this drug acts only on tissues supplied by the sympathetic nervous system. While many observers have obtained negative or indefinite results, others, including Plumier, Starling, and Sharpey Schafer, have brought forward good evidence that adrenaline constricts the pulmonary vessels as it does the systemic. This suggests that the vessels have a sympathetic control, although in the light of more recent knowledge referred to below, this has not been reinvestigated.

By the introduction in 1919 by Sharpey Schafer of a convenient method of recording the pressure in the pulmonary artery new light has been thrown on the pulmonary circulation, and amongst the findings has been the fact that the effect of drugs which act on the circulation was greatly modified by anaesthetics.

I first noted that the effect of drugs on the pulmonary circulation would be much more easy to demonstrate on decerebrate animals, or animals under light ether anaesthesia, than on those anaesthetized with chloroform. For example, it was shown that the action of amyl nitrite on the pulmonary circulation can be prevented by deep anaesthesia. An investigation is in progress\* to find out to what extent the functional activity of the lung tissue may be impaired by anaesthesia. It has already been shown that the action of histamine, now acknowledged to be a pulmonary constrictor (Dale and Laidlaw, Morris), may be similarly abolished.

There is evidence, too, that the action of adrenaline on the pulmonary circulation may be prevented while the systemic effect may be unaffected. This has occurred where all possibility of backward pressure through an incompetent mitral valve and cardiac effects have been excluded.

When the literature of the subject is surveyed it is found that the most probable reason for the negative or variable

results of different investigators, largely in the days when chloroform was in more common use, was the effect of the anaesthetic. The effect of anaesthetics is not necessarily excluded in lung perfusion experiments, as the animal is under an anaesthetic immediately prior to death, and with the cessation of blood supply and anaesthetic the anaesthetic has all the better chance to produce its bad effects. In the positive experiments of Sharpey Schafer and of Starling, referred to above, volatile anaesthetics were not used except in the preliminary anaesthetization, but chloral and chloralose respectively.

This is not the first time that attention has been drawn to the action of anaesthetics on the lungs. In this JOURNAL, in 1880, McKendrick, Coats, and Newman described complete stoppage of the pulmonary circulation of the frog as the result of chloroform anaesthesia, with actual destruction of the lung epithelium.

When the evidence put forward by Flemming is considered, the importance of the local effects of anaesthetics on the lungs will be seen. He might also have added to his list the fact that a piece of muscle exposed to chloroform vapour is killed with great rapidity, a fact which is made use of in the thermopile experiments of Hartree and Hill on heat production.

My results so far agree with those of Flemming on isolated tissues. Recovery from the pulmonary effects occurs after ether, but after deep and prolonged anaesthesia with chloroform recovery is the exception. The actual death of tissue in the lungs as a result of the anaesthetic does not appear to be a remote possibility—indeed, may be easily considered the natural sequel. It is outside the scope of this paper to consider the evil results of such lethal action, but obviously the symptoms discussed at the Glasgow meeting might readily follow. That the absorption of toxic products from such dead tissue should produce delayed chloroform poisoning seems most reasonable.

Another function shown to be abolished is that of the bronchioles, which limit the amount of air passing in to the alveoli. Brodie and Dixon first demonstrated that the vagus no longer caused bronchiole constrictions under deep anaesthesia. The muscles or their nerve supply were considered to be paralysed by direct absorption of the anaesthetic through the mucous membrane. I have demonstrated that the action of adrenaline on the bronchioles may similarly be prevented by deep anaesthesia.

Now the abolition of the bronchiole function must necessarily throw a greater strain on the alveoli and cause them to be exposed to particles which otherwise would not reach them. Even if actual death of tissue does not occur, the mere loss of this protective mechanism temporarily must expose the lung to possible damage.

The investigation is proceeding, but from the results already obtained it is seen that the local effects of the common anaesthetic cannot be ignored, not only from the purely experimental standpoint, but also from that of the clinician. Although anaesthetics may be given to thousands of cases yearly without effect, it must be urged that we are still without an ideal anaesthetic for general use.

From the evidence given it is seen that deep or prolonged anaesthesia with ether, and especially with chloroform, should be avoided whenever possible. It is suggested that narcotics should be more extensively used to supplement volatile anaesthetics.

## INTESTINAL OBSTRUCTION FOLLOWING ACUTE APPENDICITIS AND PERITONITIS.

BY

P. F. MCFARLAN, M.B., Ch.B., F.R.C.S. EDIN.,

SURGEON TO STIRLING ROYAL INFIRMARY.

In the case here reported adhesions must have begun to form immediately after the first operation. The second operation was undertaken because of the increasing distension and in spite of the fact that there was no vomiting and that the patient's bowels had moved on the previous day. The part of the ileum opened on the fifteenth day was below the site of obstruction, which had been liberated at the second operation; the opening acted simply as a safety valve, and by relieving distension allowed the intestines to recover tone.

On February 6th, 1922, a man aged 20 was sent in to Stirling suffering from acute appendicitis. His illness had started suddenly thirty hours, approximately, before admission. When I first saw

\* The research is being assisted by a grant from the British Medical Association.

him he had a temperature of  $101^{\circ}$  and a pulse of 112. He was very tender all over the lower half of the abdomen, and there was marked muscular rigidity. He gave no history of previous attacks, and in all other respects he was healthy and well developed. He was operated on a few hours after admission, and a gangrenous appendix with two concretions was removed. There was a considerable quantity of pus in the pouch of Douglas, and there was marked injection of all the peritoneal surfaces which came into view. A corrugated rubber drain was introduced into the pouch of Douglas. He was given normal saline and 6 per cent. solution of glucose alternately every two hours by the bowel, and morphine  $\frac{1}{2}$  grain on the first night. On the day following he was able to take liquids by the mouth and had no vomiting, so the saline and glucose enemata were stopped. His temperature came down to normal on the morning after the operation, and never rose again above  $103^{\circ}$ . His pulse came gradually down to 96 on the third day, and to 89 to 84 on the fifth day. The tenderness and rigidity also passed off in the first three days. In all respects he appeared to be making a good recovery, except that from the evening of the second day he began to complain of intermittent pain, of slight distension, and of a desire to have his bowels moved. Because of this constant demand on the part of the patient, on the evening of the third day he was given a small turpentine enema, which was returned coloured with a little constipated faecal matter. His distension continued slowly to increase, and his discomfort was more marked. He was given castor oil on the afternoon of the fourth day, and another turpentine enema. The bowels moved slightly that night, and they moved three times the next day, aided by  $\frac{1}{2}$  grain of calomel hourly up to 2 grains and another enema. Still the distension did not diminish and his discomfort was no less. He was given nuxvomine  $\frac{m\bar{x}}$  on the night of the sixth and seventh days. He still had no vomiting. His tongue by this time was dry and coated. His pulse remained at about 88, and his temperature never rose above  $99^{\circ}$ .

On the seventh and eighth days he had several small motions, mostly liquid, but his distension increased and also his discomfort, and owing to the distension the incision for the removal of his appendix stretched and broke down. Still no vomiting.

On the ninth day I opened the abdomen in the middle line and found the small intestine very much distended above a dense adhesion which bound the small bowel firmly to the mesentery of the pelvic colon. There were two other adhesions between the small intestine and the floor of the pelvis. These adhesions were all separated and the raw areas were covered over. A small quantity of pus was found in the pouch of Douglas. The distended bowel was all replaced in the abdomen, and I put a rubber drain into the pouch of Douglas, which was removed the next day. He had some sickness after this operation, and some dilatation of the stomach, which improved rapidly with gastric lavage. He was given pituitrin and enemata, and castor oil by the stomach tube thirty hours after the second operation. The next day he had a copious liquid evacuation. He went on fairly well for a day or two, but never was quite comfortable and his distension did not diminish. Then he got worse again, and on February 21st—that is, fifteen days after the first operation—I opened the ileum, which was presenting at the original appendix incision, and stitched a small rubber tube into it. This tube drained freely at once and continued to do so for several days. His distension came gradually down and his bowels moved freely two days after. He made a slow recovery, being troubled with diarrhoea for some days, but he was able to go home six weeks after the date of his admission with all his wounds healed. By the third week of April he was wonderfully well. There was, however, a hernia at the site of the appendix incision.

Twenty years ago we were taught to give aperients and enemata to similar cases on the second day after operation. Now the practice is to withhold all stimulants to peristalsis either by the mouth or rectally till "convalescence is well established." Mr. H. W. L. Molesworth,<sup>2</sup> in an excellent article on the after-treatment of acute abdominal disease, recommends giving no purgative till after the patient's bowels move, and he advocates a fairly liberal use of morphine. During the last two years or so it has been my practice not to give a purgative till the fifth or sixth day after operation. I give morphine readily for the first twenty-four hours; after that I try to avoid giving it.

We have had several cases of intestinal obstruction recently following pelvic peritonitis, and these cases have made me wonder if it is wise to withhold purgatives so long in all such cases. Is it not possible that by keeping the bowel at rest for six or seven days, with a fairly free use of morphine, we encourage the formation of adhesions and give them time to contract and so pave the way to intestinal obstruction?

## MEDICAL, SURGICAL, OBSTETRICAL.

## THE CORRECTION OF MALPOSITIONS: THE RATIONALE OF THE PADDED BINDER.

IN using the method of the padded bandage to produce a favourable version or rotation the aim is to apply localized pressures in the same direction as we should choose for pressure applied manually. The difference is that by the pads the pressure is exerted with less intensity but over a longer time than by the hand. The mechanics of the problem is very simple. The binder applied in a circle exerts nearly equal inward pressure at each point of its course, but when pads are applied under it the inward pressures through the pads are greater. Being applied at opposite points of the child's body these pressures give the mechanical couple which is necessary if we are to produce a rotation. To obtain the greatest number of successes it is important to individualize the cases by selecting the most effective points for the placing of the pads and the best form of each pad for the application of pressure to the underlying part of the child's body, but the essential in every case is to secure two pressures which are in opposite directions at points as remote as possible from the line which is the axis of the rotation we desire.

## HYSTERICAL ELBOW.

THE case of hysterical simulation of fracture associated with hyperextension of the elbow-joint, recorded by Drs. H. C. Woodhouse and F. Carlton Jones (December 16th, 1922, p. 1171), induces me to publish the following similar case:

On May 6th, 1921, an intelligent girl, aged 14, applied to me for treatment at Bootle Borough Hospital. The history was that she had had a slight fall on some stairs and had struck the back of her right elbow, which at once became stiff and could not be flexed.

The elbow was found to be hyperextended to about 15 degrees, and the arm was rotated outwards, the forearm fully supinated, and the wrist and fingers extended. The patient complained of pain in the elbow-joint, but no sign of local trauma was found. When attempts were made to flex the forearm the triceps was felt to contract and the amount of contraction was found to vary with the force applied. The left elbow could readily be extended to a similar degree as the right, but no other joint possessed an abnormal range of movement. The patient volunteered the information that this was her first day in domestic service.

A diagnosis of hysterical elbow was made, and I proceeded to take a photograph of the condition. While adjusting the camera tripod I noticed that the gross hyperextension gradually disappeared, and that the forearm became pronated. Pretending that I was about to move her chair into a better light I seized the girl's arm, and—without difficulty and against no resistance—fully flexed the elbow.

On June 11th, 1921, the patient returned with a history that she had gone back to domestic service and had struck her arm again, when the condition had recurred. On this occasion there was less hyperextension, and the wrist and fingers were in no fixed position, but again the arm was rotated outwards and the forearm supinated. I suggested to the patient that the spasm would pass off when the pain from the blow had subsided. I persuaded the mother that the condition was hysterical, and she promised to show no sympathy: at the same time she was advised to find more congenial work for the girl. The patient did not again apply for treatment while I was at the hospital.

London Hospital.

## THE ETIOLOGY OF OPTIC ATROPHY.

WITH reference to the report of the discussion on the etiology of optic atrophy at the recent meeting of the Section of Ophthalmology of the British Medical Association (JOURNAL, December 16th, 1922), and more especially with reference to Dr. C. O. Hawthorne's remarks on the neuritis of acquired syphilis, which he said was a very exceptional event in the early stage of the disease, the following case may be of interest.

A woman, aged 25, was seen in the Finger Klinik here a few days ago, when she showed a typical syphilitic leucoderma of a week's duration. Inquiry elicited the information that infection had taken place about four months previously. The cerebro-spinal fluid gave a positive Wassermann reaction. Three days later the same patient was encountered in the ophthalmological department, and then showed a typical acute double optic neuritis.

On the authority of Professor Kyrle, of the Finger Klinik, it can be stated that most cases of syphilitic leucoderma show

a positive Wassermann reaction in the cerebro-spinal fluid at the time when the skin lesions first appear—that is, in the secondary stage of the infection. This he takes as undoubted evidence of a syphilitic meningitis at this early stage of the disease. May it not be, then, that the optic neuritis which occurs in the early stages of acquired syphilis is to be regarded, not as an isolated effect of the syphilitic poison upon the optic nerves, but rather as evidence of a widespread involvement of the central nervous system in the form of a syphilitic meningitis?

WILLIAM L. TEMPLETON,

Vienna, Austria.

## Reports of Societies.

### INFECTION OF TEETH AND GUMS.

A DISCUSSION on the clinical, pathological, and radiological aspects of infection of the teeth and gums took place at the Medical Society of London on December 11th, 1922, with the President, Lord DAWSON of PENN., in the chair.

Sir WILLIAM WILCOX introduced the subject in a paper printed in full at page 53.

Professor J. McINTOSH related particulars of his work, with Mr. Warwick James and Professor Lazarus-Barlow, on the isolation of a bacillus which they believe to be the cause of dental sepsis, and to which they have given the name of *Bacillus acidophilus odontolyticus*. He then briefly summarized present day bacteriological knowledge with regard to pyorrhoæa alveolaris. The type of organism commonly associated with pyorrhoæa was the streptococcus. *Spirochaetes* and *amoebæ* had also been found, but he thought they did not play any etiological part. They were chiefly to be found in the grossly contaminated pockets and not in the deeper regions.

Dr. J. H. WOODROFFE gave an account of the x-ray appearances attending sepsis, which he illustrated with some dental radiographs. He also touched on the relation between the doctor, the dentist, and the radiologist. The doctor was frequently anxious for more radical measures than the dentist thought desirable, and there was a tendency for the radiologist to be drawn into the controversy. He did not think that the radiologist should be expected to say what teeth should be extracted; this should be a matter for discussion between doctor and dentist.

Sir FRANK COLYER said that as a dental practitioner one of the most difficult things he had to decide was whether teeth should come out or not. What dentists wanted to know from the radiologist was whether the bone behind the tooth was deeply infected. Patients under 50 who were definitely suffering from general symptoms, and in whom the bone showed definite trouble, should without a doubt have their teeth extracted. The best results following the removal of dental sepsis in general conditions were in patients under 50 whose tissues had power to recuperate.

Dr. GREGORY EVANS gave an account of a case, to which Sir William Wilcox had also alluded, in which a patient had malaise and irregular pyrexia due to septic teeth. The extraction of six teeth was followed by a profound streptococcal toxæmia. The removal of the remaining infected teeth was followed by a gradual disappearance of the toxæmic condition. He showed the blood picture obtained in this case, and indicated the changes in the differential count, which signified in some cases the absorption of poisons from dental sepsis.

Dr. WILLIAM HUNTER referred to the fact that in 1900 he read a paper before the Odontological Society of Great Britain on the relation of dental diseases to general diseases. The paper created a good deal of interest, largely because of the previous investigations by Professor Miller in Berlin, which had emphasized the magnitude of the infection and the variety of the flora. His own contribution drew attention to the foci of disease in the month which came under the direct observation of the physician. The present discussion was the first which had taken place on oral sepsis since the subject originated twenty years ago, in striking contrast to the keen interest shown in the United States. Since his original paper the x-ray method had made its appearance, but he hoped that physicians would maintain their own individuality and form an independent judgement without implicit reliance upon one piece of evidence such as an x-ray picture.

Dr. P. WATSON-WILLIAMS, with his colleague Mr. W. R. ACKLAND, showed some stereoscopic odontograms, and spoke

further on infections of the teeth and gums in relation to the ear, nose, and throat, which had formed the subject of a recent communication by him to the Odontological Section of the Royal Society of Medicine. The radiograph, he said, would show a good deal which was not to be discovered by other means, but it needed cautious interpretation.

Lord DAWSON, in closing the discussion, said that this subject afforded a very good example of the necessity for team work. What was wanted was some really connected work upon the subject to which dentists, radiographers, clinicians, and bacteriologists would all contribute; these should take a selected number of cases and follow them through. In spite of many interesting contributions to the discussion, the evidence available as to the effects of dental sepsis was extraordinarily thin. There was a great deal of sloppy thinking on this subject. Many members of the public now had had their teeth extracted, to the detriment of their appearance, and very often without benefit to their health. Hardly a week passed by without some example of the kind coming to his knowledge. One recent case was a young woman who had had her teeth taken out for scroderma, without any benefit to her condition. If the teeth were definitely and markedly affected, the appropriate measures were, of course, called for; or if the patient was suffering from a febrile disease which had potentialities of evil it seemed a rational and proper proceeding cautiously to remove the teeth. But the cases in which he found difficulty were those of people with vague ill health—people who had no real illness, but were not quite up to the mark—or, again, people with an illness whose cause eluded the physician. There he saw grave difficulty in removing the teeth just on the chance that they might be the cause of the trouble. In very many cases there were no means of tracing the causal relationship to the teeth. He could not bring himself to believe that so many diseases as Sir William Wilcox had enumerated could be produced by oral sepsis. He knew of no one cause which could produce so much. Sir William had even deprived part of its responsibility for gout! Were his catalogue justified the wonder was that a larger proportion of mankind were not diseased, or that, of the large numbers of people with oral sepsis, comparatively few got any of these diseases. Lord Dawson admitted that in rheumatism and other diseases there were striking examples of improvement following the treatment of oral sepsis—so pronounced that one was bound to say in some instances that this disease must be caused by oral sepsis. But in a large number of diseases ascribed to oral sepsis he believed that the direct influence of this condition was far less than it was now the custom to take for granted. Take duodenal ulcer: he did not believe that there was the smallest indication that duodenal ulcer was produced by sepsis of the month.

Sir WILLIAM WILCOX agreed that every case should be approached with a critical mind. It was a great responsibility to advise the extraction of a patient's teeth, and there should be adequate local grounds for such extraction. Much yet remained to be done in finding the scientific proofs for the etiology of many of the common diseases he had instanced, and he agreed with Lord Dawson that there was no department of medicine in which team work was likely to be more valuable than in the investigation of oral sepsis.

### SURGICAL TREATMENT OF RENAL CALCULI.

The Section of Surgery of the Royal Society of Medicine on January 3rd held a discussion on renal calculi, more especially their surgical treatment. The President, Mr. JAMES BERRY, announced that Sir J. Thomson Walker was unable to take part owing to absence from London.

Mr. W. SAMPSON HANDLEY opened with a few remarks on the pathogenesis of renal calculi. From personal observation in two cases he was convinced that the first step in the formation of a calculus might be the appearance of a cyst in the cortical substance. In this cyst a calculus was deposited later, and came to light when the cyst ultimately ruptured into a calyx. He would not suggest that this mode of formation was frequent, but unless it was recognized the chances of overlooking a stone during operation were increased. He gave particulars of the cases he had seen which bore on this point, and showed a specimen (No. 3618) from the museum of the Royal College of Surgeons of a kidney which, when split open, was found to contain a calculus wedged in the pelvis, while in the middle convexity of the kidney was an empty cystic cavity, ovoid in form, measuring 1 in. by 1/2 in. in section,

and communicating by a narrow oval opening with the dilated calyx which led down to the blocked pelvis. He believed that this specimen represented a late stage in the history of cystic calculus.

He then addressed himself to a review of the methods of removing stone from the kidney. He regarded the operation of nephrolithotomy or the splitting of the kidney as an unscientific procedure, to be reserved for kidneys with a very large calculus, and for cases in which, owing to a short pedicle or a deep loin, the necessary exposure for an incision into the renal pelvis could not be effected. In the last ten years he had only twice been driven by necessity to do a nephrolithotomy in preference to pyelolithotomy. Sir J. Thomson Walker, in his *Genito-Urinary Surgery*, adopted too detached an attitude in discussing the rival claims of nephrolithotomy and pyelolithotomy, and yielded too much territory to the former operation; but he made no doubt of his real preference for the second operation when he recommended it for removal of a stone from a solitary kidney. There was something to be said for a restricted nephrolithotomy. Hartmann of Paris had insisted that if upon exposure of the kidney a stone could be plainly felt in its substance and near to its surface, and the radiograph had shown the stone to be single, it was best to cut down upon it through the renal substance; the French surgeon declared that a small incision only was necessary, little damage to the kidney substance was done, and the operation had the merit of directness and simplicity. When a stone or stones could not be palpated externally some surgeons recommended that the pelvis should be reached by two incisions, one in the upper and one in the lower third of the kidney, opening the uppermost and the lowest calyx. The speaker did not believe, however, that free access to the pelvis could be obtained in this way, and the same objections applied to unipolar nephrolithotomy. In his belief the kidney should be explored by way of the renal pelvis directly. The cavity of the pelvis occupied to the kidney the relation of a manhole to a drainage system, and like the manhole could be opened and closed easily without injury to the rest of the system. He read Thomson Walker's description of the technique for pyelolithotomy. Some surgeons, especially Hartmann, maintained that it was unnecessary to suture the incised pelvis, and Mayo also was said to have abandoned suturing. The insertion of a layer of sutures in the pelvis was certainly tedious, and increased the strain of the operation on the patient's vital powers. Nevertheless the firm, immediate, and accurate closure of the pelvis after incision was an end desirable in itself if it could be done easily and simply.

Mr. Handley then described a method of "subcapsular pyelolithotomy" evolved by him:

The kidney, having been exposed by a lumbar incision, is brought up to the surface intact in its capsule. An incision about 3 in. long, and following the long axis of the posterior surface of the kidney, is made through the fibrous capsule. Two pairs of forceps are clipped upon the posterior edge of the incision in the capsule. While these are situated a pair of dissecting forceps is insinuated beneath the capsule in the direction of the pelvis until an entrance to the hilum of the kidney is reached. Here the capsule, or one layer of it, leaves the kidney and passes on to the posterior surface of the pelvis. The forceps or dissector enlarges the pocket formed beneath the capsule until, at its bottom, the line of entrance of the pelvis into the substance of the kidney is reached. A knife is now taken, and with its point the posterior surface of the pelvis is cautiously incised at the bottom of the capsular pocket in the long axis of the kidney. The forceps, or if necessary the finger, can now be introduced into the pelvis, the stones present in it removed, and the opened recesses explored. When the opening in the pelvis has served its purpose it can be completely and rapidly closed by three stitches uniting the edges of the original incision in the capsule on the posterior surface of the kidney.

He had performed this operation in nine unilateral cases of renal calculus and in two bilateral cases. In all of them the calculi were small and lay in the pelvis or in the calyces, from which they could be extracted by way of the pelvis. In none of the cases did any complications arise. In dealing with a compound branched pelvis, instead of opening the main pelvis one might possibly open the two branches, and so be confronted with two cavities instead of one, which would add to the difficulty of the operation; but his subcapsular method had the advantage that the flap, which was common to both cavities, would of itself reconstitute the pelvis when placed in position. He also emphasized the value of digital examination. For certain purposes in surgery the gloved finger, gently used, was not merely the safest but the only instrument to supply the necessary information.

Mr. FRANK KIDD was glad that Mr. Handley had emphasized the danger attending the splitting of the kidney—a procedure

which should hardly ever be needed. When it was done it should only be after the blood vessels had been controlled temporarily. Most urinary surgeons nowadays had adopted the method of using a finger in the pelvis and a finger on the surface of the kidney, in preference to splitting the kidney. Great help could be afforded by exploration with the finger. The danger of secondary haemorrhage after the splitting was very considerable. Often the patient did not bleed so much at the time, but when the catgut ligatures separated about the tenth day very severe secondary haemorrhage might occur. He thought Mr. Handley's subcapsular method, if taken up at all generally, might lead to accidents. Mr. Handley had carried it out in only a few cases; if done in a hundred cases he believed it would be found that in perhaps 5 or 10 per cent. serious haemorrhage occurred from an artery which came down from the top of the kidney posteriorly, and often ran very low. He himself believed that the longitudinal incision in the pelvis, as described by Thomson Walker, was the safer for routine purposes. The danger of fistula after pyelolithotomy he believed to be entirely misconceived. Fistula followed only when some of the stone was not removed. A little bit of the stone might be broken off and get into the ureter, blocking it and causing fistula. Urinary surgeons had tried at various times to apply x rays to the operating table. He had been lately in America, watching the Mayos, who had at last got an x-ray apparatus which worked satisfactorily (though not without occasional danger) on the operating table, so that fluoroscopic examination of the kidney was possible at the time of operation. It was rather disconcerting to find how often the x rays showed that all the stone had not been removed. He doubted whether, without some means of combining x-ray examination with the actual operation for stone in the kidney, justice was done to the patient. For bilateral calculus he believed that both kidneys should be incised at the same operation.

Professor F. HORDAY, speaking from the veterinary point of view, said that renal calculus was common in animals, and as some animals were herbivorous only, some carnivorous only, and some omnivorous, there was scope for interesting observation. Renal calculi were found in the horse, the dog, the cow, the sheep, and the pig. In the horse this condition was quite common; sometimes the involvement was such that nothing was left of one kidney but the mere capsule. As long as one kidney was functioning it was remarkable how long the animal could go without showing any outward indications. The same held true of the dog. In the sheep, pig, and cow the calculi were observed less commonly, but this was probably because these animals did not live the long lives of the other two. The condition was met with chiefly in old or at least in adult animals, though not exclusively, for he had had a case of calculus (in the urethra) in a puppy four weeks old. In a large canine practice in London he saw twenty or thirty cases every year. If an operation was done, the procedure generally was to remove the diseased organ. Radiography had been of the greatest service, and with an animal suffering pain in the region of the kidneys, even though it had not haematuria or any other indication of stone, it was the common practice to obtain a radiograph.

Mr. J. SWIFT JOLY said that he endeavoured in each case to select the operation which would do least damage to the kidney. No rigid rule could be proclaimed as to the relative merits of nephrolithotomy and pyelolithotomy. Much depended, to begin with, upon the patient's physique. In a fat person, with a thick abdominal wall, the kidney perhaps could not be got sufficiently out of the loin to do pyelolithotomy with safety. Again, the relative size of the stone to the renal pelvis was a factor to be taken into account. If a stone was definitely in the renal pelvis not extending up into the calyces a pyelolithotomy could almost always be done, provided the kidney could be brought out of the loin. There was no real limit to the size of the true pelvic stone which could be got out through the pelvis. Recently he removed two stones from a kidney pelvis through a pelvic incision, the larger stone being about the size of a hen's egg and the smaller about the size of a cherry; but the patient had a dilated pelvis, and it was easy to get them out. But when, owing to branching, the stone involved calyx as well as pelvis it was not always possible to get it out through the pelvis, and to attempt that operation was to do more damage to the kidney than by making a clean cut through the kidney itself. When there were stones both in the pelvis and in the calyces the line of conduct would be governed chiefly by the amount of dilatation of the pelvic-calyx system. If the

kidney was dilated and the pelvis and all the calyces dilated, these stones could be got out through the pelvis quite comfortably; but if, as often happened, though the pelvis was dilated, there was a very narrow opening between pelvis and dilated calyces, he thought it wrong to try to enlarge that opening either by dilatation or by cutting through the pelvis. It was much safer to cut through the cortex in such cases, and while taking the pelvic stone out through the renal pelvis to take the smaller stones out by way of the cortex. He went on to consider the methods of exploring the kidney in those uncertain cases in which the  $\pi$  rays showed a small shadow, whose exact position was uncertain, and nothing was very palpable. Generally the  $\pi$  rays gave a good idea of the locality of the stone, and this greatly simplified the operative technique. But if quite in the dark as to where the stone was the rule he followed was first to look at the renal pelvis. With a big pelvis, extending well out from the kidney, he opened it and passed his little finger in and explored the calyces one by one. If he could find nothing there he made an incision over the lower third of the kidney and cut down on the lower calyx. One was given a much more direct line of action from the cortex downwards than from the pelvis upwards. This plan of exploration could be continued, but it was rarely necessary nowadays, for usually the surgeon was able to have a map of the position before he started.

Mr. H. W. WILSON said that if the kidney cortex was opened the danger of secondary haemorrhage was always to be feared. Yet the surgeon could not deal effectively in all cases by working through the pelvis, and he was bound to leave stones behind if this were attempted: but the secondary haemorrhage which followed the other course was very serious, and he desired to know from his colleagues whether they were aware of any means of averting it.

Mr. R. H. J. SWAN agreed with all the speakers that a perfectly open mind must be kept as to the kind of operation to be performed. In the great majority of cases, when the surgeon had got the kidney thoroughly exposed, the line of procedure would be perfectly obvious. Secondary haemorrhages after nephrolithotomy were very serious, and he had had to do a nephrectomy to save the patient's life. At the same time he was convinced that not every stone could be removed through the pelvis. Each case must be studied separately. He added that he had never seen a urinary fistula occurring after a pyelolithotomy.

Mr. J. E. ADAMS had found a transverse incision extremely satisfactory. He imagined that Mr. Handley had adopted the incision he described because he thought it might facilitate the healing of the wound in the pelvis of the kidney, and therefore obviate the risk of fistula. He believed the transverse incision would answer to these requirements. If the stone was large the transverse incision would necessarily be large.

Mr. SAMPSON HANDLEY, in reply, believed that members who tried the subcapsular method would discover its practical advantages. His own belief was that the posterior branch of the renal artery was pushed out of the way with the capsule; he had had no trouble from that source. In his operation the flap of the capsule guided the operator down to the line of the hilum so that he could see where the incision should be made. He could not help feeling that sometimes the severity of the double operation for bilateral calculus would be more than the patient could be expected to stand; it should be reserved for the earlier cases. The dangers of secondary haemorrhage had been alluded to; he had found vaseline gauze useful in one case to stop persistent bleeding from the kidney substance, and this might sometimes prove more efficient than sutures. He had never tried the transverse incision, which was likely to cause increased haemorrhage.

### CLEAN MILK.

At a meeting of the Liverpool Medical Institution, held on December 21st, 1922, with Mr. C. THURSTAN HOLLAND in the chair, Dr. DOBBIN CRAWFORD read a paper on the subject of clean milk. She said that America was the pioneer of the clean milk movement, but it was in England that the National Clean Milk Society was founded in 1915 with the following objects: (a) To examine the condition of milk as received by the consumer. (b) To furnish a standard of clean milk. (c) To create a demand for clean milk. It was found in 1915 that the average sample of London milk contained more than 3,000,000 bacteria per cubic centimetre—rather in

excess of the number of bacteria present in the city sewage! Tubercle bacilli were present in 10 per cent. of the samples and over 99 per cent. contained *Bacillus coli*—absolute evidence of contamination with manure. A standard of clean milk was furnished in the licences issued by the Ministry of Health in 1921 for the production of certified Grade A milk, which must contain no tubercle bacillus, no *Bacillus coli*, and not more than 30,000 bacteria per cubic centimetre at any time before reaching the consumer. It must be delivered within two days after the day of production. Every animal in the herd must be examined by a veterinary surgeon and give a negative reaction to the tuberculin test at intervals of three months.

Dr. Crawford quoted the following statistics of Liverpool milk from the report of the Public Health Department:

Of 943 samples examined in 1921, from 9 to 15.6 per cent. contained tubercle bacilli. The veterinary inspectors in 1921 found 31 cows with tuberculosis of the udder supplying milk to the city. From 80 to 90 per cent. of the samples tested contained *Bacillus coli*, and in that year diarrhoea and enteritis killed 683 infants in Liverpool.

The practical effect of grading milk was to raise rapidly the standard of the whole milk supply; it tended also to increase the consumption of milk. The cost of certified milk was 7½d. a pint, just double that of ordinary milk. The need of the moment was the education of the consumers, so as to increase the demand for clean milk. Dr. Crawford showed lantern slides to illustrate clean methods of production and their effect. These were taken at the Storms Farm Dairy, Keswick, from which she had received certified milk during the past year. The reports of this milk by the Ministry of Health showed that when seventeen to eighteen hours old it contained no *Bacillus coli*, and an average of only 242 bacteria per cubic centimetre. She had persuaded a dairyman in Wallasey to retail this milk, but, owing to lack of demand, it was not procurable in Liverpool.

### Dermatitis in Bakers.

Dr. OSCAR DE JONG read a note on the etiology of dermatitis in bakers. Dr. de Jong said that bakers' dermatitis occurred in bakers employed in bakeries where the hands are used in mixing, not in bakeries where machines are used. Investigations showed that the flour used was not responsible, as no cases of dermatitis were found in men employed in flour mills who were constantly handling flour. Similarly, no cases were found in men handling or preparing yeast. The condition was due to immersing hands and arms in the salt solution added to the flour, which was about 3.6 per cent. in strength. Owing to the temperature of the bakehouse and the ovens the salt crystallized on the arms of the workman, and the process of kneading worked the crystals into the skin, setting up a dermatitis in susceptible individuals. Cure was obtained by rest from work and local treatment. Dr. de Jong concluded his note by suggesting prophylaxis by the use of a spray of fresh water after mixing the salt solution and at periods during kneading. The condition relapsed as a rule on return to work.

Dr. FRANK H. BARENDT alluded to the terminology of this affection, and showed that it was well known in bygone ages. He emphasized the fact that the proportion of those suffering from bakers' itch was but slight. In spite of the number of possible excitants and a too vigorous use of soap and water in ablution that should not be overlooked, one was compelled to admit the presence of idiosyncrasy. Dr. Barendt considered that nevertheless all the necessary preventive measures to which Dr. de Jong had drawn attention should be taken, and every case should be treated *sui generis*.

### "Acute Abdomen" in the Child.

Mr. W. A. THOMPSON read a paper on the acute abdomen in the child, based on 100 consecutive cases. These included 53 cases of acute appendicitis, 15 of which had general peritonitis; of these, 5 died. There were 27 intussusceptions, the great majority occurring between the fourth and eighth months; 21 recovered, 6 died, three following resection and lateral anastomosis, one of which lived nineteen days, and one case, moribund on admission, died soon after reduction had been performed. The reduction should be intra-abdominal. Many cases were associated with enlarged ileo-caecal glands, some of which were connected by bands to the gut immediately in front of the original apex of the intussusception. Mr. Thompson explained how these might cause an intussusception, and how a much enlarged gland caused a recurrent

incipient intussusception. The majority of cases commenced as ileo-ileal—66 per cent. Of 8 cases of acute intestinal obstruction operated on 5 recovered; 3 cases of strangulated hernia had been met with in over 1,000 of Mr. Thompson's cases; they all recovered.

### MILITARY SERVICE AND HYGIENE.

A MEETING of the Naval, Military, and Air Force Hygienic Group of the Society of Medical Officers of Health was held on December 1st, 1922, when the President, Major-General Sir WILLIAM MACPHERSON, K.C.M.G., delivered his presidential address on "The influence of military service on hygiene." By historical outline he showed how some indication could be gathered of the influence that military service had brought to bear on questions of health preservation and prevention of disease. Maintenance of physical fitness, physical training, hygiene of the march, relationship between food and energy, hygiene of clothing, camp sanitation and all it implies (such as water supply, camp sites, hospital accommodation, barrack rooms lighting and ventilation, etc.), prevention of specific diseases, and education of the individual in sanitary habits, were all dealt with in turn. The President referred to the workers of ancient times, such as the numbering of the men by Moses "from 20 years old and upwards, all that were able to go forth to war"; to Vegetius in the fourth century A.D., who laid stress on the graduated training of men; to the sports and exercises of the ancient Greeks; and to the care of bodies as advised by Alexander the Great for obtaining and preserving physical fitness. Mention was then made of the more recent pioneers, such as Sir John Pringle, Robert Jackson, Edmund Parkes, and Lieut.-Colonel Garrison of the U.S. army. Lastly, Sir William Macpherson's references to the preventive investigations of David Bruce and Horrocks in regard to Mediterranean fever, of Almroth Wright and Leishman in regard to inoculation against enteric fever, of Manson and Ronald Ross in regard to malaria, and of the workers on cerebro-spinal fever in the recent war, brought a most instructive address to a close.

Lieut.-Colonel H. R. KIRKWOOD, who occupied the chair, expressed the regret of those members who were unable to be present, and the meeting concluded with a cordial vote of thanks to the President, proposed by Surgeon Rear-Admiral Sir PERCY BASSETT-SMITH, and seconded by Major-General W. W. O. BEVERIDGE.

### BLUE SCLEROTICS AND MULTIPLE FRACTURES.

A MEETING of the Midland Medical Society was held in the Birmingham Medical Institute on December 20th, 1922, when the President, Dr. PUNSLOW, took the chair, and about forty members were present.

Mr. A. W. NUTHALL showed the cases of a father and two daughters, who exhibited the combination of blue sclerotics and multiple fractures. Mr. Nuthall shortly reviewed the literature of this interesting condition. The father had over thirty fractures, and both daughters had fractured several bones. These cases were discussed by Dr. A. P. THOMSON, who knew of four families exhibiting the same symptoms. He stated that in these cases the fractures were more frequent up to the age of 10 years, and after that age became much less frequent.

#### Paroxysmal Tachycardia.

Dr. EMANUEL showed a man of 52 who for some years had suffered from attacks of a rare form of paroxysmal tachycardia.

In the attacks, which lasted from two or three hours to three or four days, the pulse rate was slow—34 to the minute—and consisted of runs of 2, 3, 4, or 5 regularly spaced beats at a rate of 82. These runs were separated by pauses of three to seven seconds in which no beats were felt at the wrist, and no heart sounds were audible over the præcordium. The electrocardiogram showed that the silent pulse periods corresponded to paroxysms of ventricular extra-systoles arising in the right ventricle at the rate of 173 to the minute, as many as 17 being counted in a single paroxysm. In the paroxysm the ventricle drove the auricle with a reversed heart-block of 2 to 1 and sometimes 3 to 1. During the intervals between the attacks the pulse was regular, at a rate of 60 to 66 to the minute. Dr. Emanuel said that Dr. Hart described a similar case in *Heart* (1912-13, vol. iv, p. 128). Those cases were clinical counterparts of the paroxysmal tachycardia experimentally produced by Sir Thomas Lewis by ligation of the right coronary artery, described in *Heart* (1909-10, vol. i, p. 98).

Dr. Emanuel's case was discussed by Dr. BUNTING, Dr. WILKINSON, and Dr. MELSON.

### Pasteurization of the Milk Supply.

Dr. JOHN ROBERTSON, medical officer of health for Birmingham, read a paper entitled "The pasteurization of the milk supply in Birmingham," and emphasized the following points. About 75 per cent. of the milk supply in Birmingham was at present pasteurized or sterilized in order to prolong the life of the milk. Several firms sterilized milk in bottles. Milk should be efficiently pasteurized, then cooled to a temperature of 40° F. and bottled in a bottle which had been sterilized. Such milk was safer than any other variety of milk, pathogenic organisms of tubercle, enteric fever, scarlet fever, sepsis, etc., being killed. No contamination could take place until after the bottle had been opened in the consumer's house. Probably less damage to vitamins was caused than by nursery heating. The keeping properties were also better. Because the milk was clean and of good quality and safe more milk was used. Dr. Robertson's paper was discussed by Dr. MELSON and Dr. ROBB.

### UNSATISFACTORY APPENDICECTOMY.

At the meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, held on December 15th, 1922, with the President, Sir W. DE C. WHEELER, in the chair, Mr. W. DOOLIN, in a paper on "Some unsatisfactory appendicectomies," said that the so-called appendicular dyspepsias cover a varied group of living pathological changes, whose differential diagnosis is not always easy. For many of these patients appendicectomy, whilst technically easy of accomplishment, failed to relieve symptoms; further, many appendices were removed without sufficient pathological justification for the operation. In the out-patient department at St. Vincent's Hospital, of 29 patients who had undergone appendicectomy, either there or elsewhere, for the relief of "chronic appendicitis," 20 had been completely relieved of their symptoms by the operation, but in 9 cases symptoms persisted after operation. The majority of the unsatisfactory results were in females. Eight of these were admitted to hospital for further study, and a second operation showed the continuation of trouble to be due in 3 cases to caecum mobile, in 3 to tubercle, and in 2 to pericolicitis. Detailed notes of the cases were given. A common pre-operative syndrome was to be found in

these patients, consisting of . . . . . stant pains situated below or to the right of the umbilicus. Tenderness over McBurney's point was inconstant; in many women painful flatulence was the dominant complaint. The whole symptom complex was an unsatisfactory one upon which to recommend appendicectomy offhand. Other observers, notably Gibson of New York and Enriquet of Paris, had reported anything from 25 to 40 per cent. of bad end-results following appendicectomy in such cases.

Four different conditions might be found responsible for such symptoms: (1) Chronic appendicitis, secondary to an acute attack, which was relieved without operation; (2) appendicitis chronic from the start, and unassociated with other intra-abdominal pathological change; (3) chronic appendicular pathology accompanying pathological changes in stomach, duodenum, gall bladder, etc.; (4) lesions of ileum, caecum, and colon, such as Lane's kink, mobile caecum, caecocoloptosis, pericolicitis. It was not justifiable to recommend operation on the case history and clinical examination alone in such cases; before operating on an alleged "chronic appendix" a complete abdominal diagnosis should be made, based on combined clinical, x-ray, and haematological findings, as recommended by the Paris school of surgery. In the author's opinion, the McBurney "gridiron" incision was responsible for many incomplete operations, and should not be taught to students. A large incision, properly placed and cared for, would heal just as quickly, and throw more light on the living pathology under the operator's hand.

The President remarked that there was very little to be learnt from operative success, but a great deal to be learnt by mistakes. He disliked the term "appendix dyspepsia." Mr. Doolin had mentioned exploratory laparotomy. The President said that it was his custom to exhaust all possible aids to diagnosis before operating, and to make at least a provisional diagnosis before opening the abdomen.

Mr. CHANCE said that, in view of the accepted fact that the diagnosis of chronic appendicitis was not to be made with certainty from the clinical findings, the history of the case, or the x-ray findings, an exploratory laparotomy was not, in his opinion, infrequently necessary. Dr. CROFTON was

not surprised that so many failures occurred, as in a great many cases no thought was taken of the infecting organism.

Mr. McCONNELL considered that the end-results in cases of this sort were not sufficiently studied. If an operation was not indicated, it would do no good; in fact, it would probably do harm. If the diagnosis of a case was not known before operation, he was of opinion that it would not be known after operation. At operation it was sometimes difficult to know whether the appendix had given rise to the symptoms or not. It was not an abnormal appendix unless some definite lesion was found when the abdomen was opened. He did not believe that x rays were of any use in detecting chronic appendicitis. In cases where a distended caecum was found, it was of great importance, and should not be ignored. He thought that Mr. Doolin's suggestion of examining patients under a screen, instead of by isolated x-ray plates, was very important, as in this way a much better idea of the case was obtained. There should be much more definite co-operation between the physician, the surgeon, and the radiologist.

Dr. SPEARES had had a number of such patients x rayed, but had not got much help in this way, except in one case, in which but for the radiologist a serious blunder would have been made. He agreed that there should be more co-operation between the physician and the surgeon; the physician had usually kept the patient under observation for some time, and so had the advantage over the surgeon in making a diagnosis.

## Rebicus.

### WAR BLINDNESS.

THE character of the blindness caused during the war differs considerably from that found amongst the civilian population owing to the high incidence of injury. Sir ARNOLD LAWSON has done good service in collecting details of the cases that passed under his hands at St. Dunstan's: the little book on *War Blindness*<sup>1</sup> which he has published gives a well balanced and interesting account of his observations.

The grand total of cases of persons blinded directly or indirectly as the result of the war, estimated eighteen months after the armistice, was 1,833 men of all ranks. The comparison between the relative number of cases of disease and wound blindness shows that disease was responsible for a little more than 26 per cent. of the total number, a proportion which is appalling enough, and for which syphilis was very largely responsible. Besides the totally blind there were a number of cases of men with indifferent but useful sight who, as the fame of St. Dunstan's spread abroad, were anxious to press their claims to twelve months' hospitality without charge, and lastly a number of pure malingers who scented pension and St. Dunstan's and whose cunning in dissembling engaged all the skill of the detective abilities of the institutional authorities.

A study of traumatic cases brings out a few general facts. Of first interest is the notable absence of sympathetic inflammation. The author did not see a single case of sympathetic disease occurring in the other eye after the smashing of one eye by shell splinters or bullet wound. A few cases were seen after some operative treatment had been carried out on one eye. He suggests that the missiles, shell or bullet, are absolutely aseptic when striking an object; it was very interesting to note how quickly and cleanly eyes would heal even after wounds of the most destructive character. At first his inclination was to remove blind stumps, but the refusal of some to submit to operation led to the observation that there was no untoward sequel, so that later cases were left untouched.

An interesting observation was that the number of cases of rupture of the choroid was large. Ruptures were often multiple, and varied in shape and position, though only three cases of solitary rupture to the inner side of the disc were seen. It would seem that there may be some element of the choroid especially liable to split, for a large number of cases showed no injury to the eye beyond the rupture, accompanied by neighbouring concussion changes and other choroidal atrophy. The direction of the blow disturbing the eye seemed immaterial to the result. There were a large number of cases where both eyes were destroyed by through-and-through penetration of the bullet. Usually the bullet took the

horizontal line of the temples. Occasionally one eye would suffer less complete damage, or part of the nerve might escape. In this way 17 per cent. of the traumatic cases were accounted for, and this suggests the desirability of improvement in the steel helmet. A brim a little broader and more obliquely set would add little to the weight and would improve the protection. Fractures of the skull accounted for many cases. Those in the region of the occiput produced a variety of field disturbances. Rarely the central field might be undamaged with a vision of 6/5, but the narrowness of the field made this acuity useless; a good field and little or no macular is infinitely more useful.

Blindness from disease was in very many cases the accentuation of existing defects. This leads the author to observe that it is not advisable to accept for active service any man whose defective sight in both eyes is due to old inflammatory disease of the uveal tract. No matter how quiet the eyes may be, or for how long a time disease has been stationary, old inflammatory mischief is always apt to recrudesce under conditions inimical to general health. If a careful ophthalmoscopic examination of all suspicious cases had been made a large number of cases of active congenital disease, such as retinitis pigmentosa or other forms of fundus disease, would have been refused, and the State would have been saved disability pensions amounting at the present time to many thousands of pounds a year. The appalling share of the total number of cases of blindness due to disease which must be allotted to syphilis will, it is hoped, have some little effect in stirring public opinion to force more attention to the subject.

### TYPHUS FEVER.

In their book on *Typhus Fever, with Special Reference to the Russian Epidemics*,<sup>2</sup> Captain J. M. MITCHELL, Dr. I. N. ASHESHOV, and Mr. G. P. N. RICHARDSON, who were all formerly attached to the British Mission to Denikin's army in South Russia, give an account of the main features of typhus fever based on their experience of the disease in that country in 1919-20. The first chapter is devoted to a consideration of the cause and prevention of typhus, including a description of the epidemic following the retreat of Denikin's army. In the second chapter, which contains an account of the clinical course of the disease and of its most frequent complications, it is stated that complications may be considered to some extent as an index of the efficiency of the nursing; with capable nurses under favourable conditions the rate of complications should be low, while with an inefficient nursing staff under unfavourable conditions, as occurred in many of the Russian temporary hospitals, the rate of complications is high. In the third chapter, which deals with the general treatment of typhus, it is said that if delousing is efficiently done cases of typhus may be treated in the general medical wards without fresh cases arising.

The last two chapters, which are written by Dr. Asheshov, are concerned with specific treatment and preventive inoculation respectively. Specific treatment is considered under the three headings of chemotherapy, including salvarsan, mercury, etc., specific serotherapy, and protein therapy. The results of chemotherapy, it is shown, are negative. Salvarsan and its derivatives are not only useless but dangerous, and mercuric cyanide and calomel, which were once regarded as specific, are now abandoned as ineffective. The use of the serum of typhus convalescents was also disappointing; although a general improvement in the patient's condition ensued, no great influence on the temperature and no marked shortening of the duration of the disease was observed. Dr. Asheshov attaches most value to the use of foreign proteins, including bacterial proteins, milk, or serum. As the presence of toxins cannot be excluded in the case of material derived from bacteria—and it is impossible to be sure of sterility in the case of milk owing to the frequent presence of spore-bearing organisms—horse serum in the form of normal horse serum, diphtheria or tetanus antitoxin, or antistreptococcal serum should be preferred. After a desensitizing dose of 0.5 to 5 c.c.m., increasing doses are given, "20 c.c.m., 40 c.c.m., and even up to 80 c.c.m., every day or every other day." Although the treatment does not shorten the disease, it has a distinctly stimulating effect on the circulatory and nervous systems. Cases so treated had rarely, if ever, any complications or sequelae. Preventive inoculation was performed by

<sup>1</sup> *War Blindness at St. Dunstan's*. By Sir Arnold Lawson, K.B.E., M.D., F.R.C.S. Oxford Medical Publications. London: Henry Frowde, and Hodder and Stoughton. 1922. (Demy 8vo, pp. 148. 7s. 6d. net.)

<sup>2</sup> *Typhus Fever, with Special Reference to the Russian Epidemics*. By J. M. Mitchell, O.B.E., M.B., Ch.B., I. N. Asheshov, M.B., Ch.B., and G. P. N. Richardson, M.B., B.Ch. London: Baillière, Tindall, and Cox. 1922. (Demy 8vo, pp. 48. 3s. 6d. net.)

subcutaneous or intramuscular injection of sterile defibrinated blood taken from a typhus patient free from any other disease (especially tuberculosis and syphilis) between the fourth and eighth days of illness. The protection conferred by this method was shown by the fact that of 195 members of the British Mission who had been completely inoculated only one developed the disease, whereas among the uninoculated the incidence was from 9 to 10 per cent.

The book contains much interesting information which is of special value as being the outcome of first-hand experience of the disease in circumstances, it is true, particularly unfavourable for elaborate clinical or pathological observations. We have noted, however, two omissions. In the first place, we should have expected at least a passing reference to the recent investigations on the pathology of the disease, which have clearly proved that typhus is a systemic disease of the small vessels. Secondly, although Plotz's bacillus is mentioned in two places, no allusion is made to *Rickettsia prowazekii*, which has greater claims than any other organism hitherto described to be regarded as the causal agent of typhus (vide BRITISH MEDICAL JOURNAL, June 17th, 1922, p. 956).

#### A TEXTBOOK OF ANAESTHETICS.

THE appearance of a new work by a well-known writer on subjects connected with the anaesthetic art, larger in scope and more complete in detail than anything he has hitherto published, cannot fail to elicit, among those interested in the subject, a certain pleasurable expectation, not unmingled with curiosity as to how his efforts would compare with those of others whose books have already become established as textbooks of anaesthesia. Dr. BLONFIELD, in his textbook of *Anaesthetics in Practice and Theory*,<sup>1</sup> modestly eschewing a preface, either of his own or other person's writing, plunges direct into chapter I, which he entitles "Introductory and Historical"; in it he defines the purpose of his labours, which is "to succeed at least in helping those who are beginning to practise this branch of medicine, and to interest those who have already gained experience."

After careful perusal of this well printed, well illustrated, and eminently readable volume, it may be said at once without reserve that the author has succeeded in the task which he has set himself. The book is free from all useless padding, but this result has not been achieved at the expense of adequate description either of methods, apparatus, or of choice of anaesthetics. The inclusion of a number of cases illustrative of the particular points the author wishes to bring out increases the general interest of the text as well as impressing facts on the mind of the reader. The physiology of anaesthesia with regard to the various anaesthetic agents employed is adequately, and at the same time interestingly, dealt with; the important work on these points being noticed and briefly commented upon. The practical aspects of the subject are clearly set out, and the choice of anaesthetics, of apparatus, and of methods of administration are explained lucidly, and without personal bias. In fact, it would not be easy to hazard a guess as to which particular piece of apparatus or which method of administration of any one anaesthetic is the favourite of the author, and this is perhaps as well in a textbook which aims at teaching not only the student but the practitioner. The advantages and disadvantages of each method are set forth clearly, and a good explanation given of each type of apparatus in common use. Nor are the more complicated methods of administration neglected, though in this case the reader is referred for details to the original papers and monographs. Chapters are included on the preliminary use of narcotic and other drugs, on the posture of the patient and its bearing on anaesthesia, on undesirable conditions of the patient during anaesthesia—their causation and treatment, on accidents and complications that may follow anaesthesia, on unusual uses of anaesthesia, on local analgesia, and on spinal and sacral analgesia. In his chapter on the fatalities of anaesthesia the author makes a well founded protest against the present custom of some coroners' courts, by which inquests are held only on those dying on the operating table, whereas in the case of those dying later in bed as the result both of operation and anaesthetic no such inquest is held. The result is to make the public believe that all deaths on which an inquest is held are due to the anaesthetic, whereas it is quite possible that the anaesthetic was not even the principal cause of the fatality.

<sup>1</sup> *Anaesthetics in Practice and Theory*. A Textbook for Practitioners and Students. By J. Blomfield, O.B.E., M.D. Cantab. London: William Heinemann (Medical Books), Ltd. 1922. (Roy. 8vo, pp. xii + 424; 48 figures. 25s. net.)

Altogether this is a book that can be confidently recommended to the student, and to the practitioner who is not in search of an encyclopaedia of anaesthesia. We may suggest that in a future edition reference should be made to Phillips's modification of Hewitt's air-way, which is a distinct improvement on the original, and to the apparatus devised by Loosely for the administration of ethyl chloride, which is very satisfactory for use in hospitals. Induction is rapid and uniform, and the patient is able to breathe air while getting used to the feel of the facepiece; this in children tends to diminish struggling prior to loss of consciousness; the instrument has the further merit that it is readily cleansed.

#### POST-OPERATION TREATMENT.

MM. ROCHARD, surgeon to the Paris hospitals, and W. M. STERN, another surgeon trained in Paris, have written a book on the general care and nursing of patients after operations, and on medical and surgical treatment of the complications which may occur.<sup>2</sup> It is directed to meet the wants of a house-surgeon at a general hospital, where the engagements of the surgeon prevent him from afterwards attending on the patients upon whom he has operated. Instruction and the examination upon what is taught tends, it is said, to become more general and theoretical, because those actually practising surgery take less part in teaching. Their attention being directed to pathology and diagnosis, students learn little of what happens after the operations, for their attendance in the wards is interrupted by the increasing number of classes. Thus a nurse has far more opportunities of learning about post-operative treatment and complications. Incidentally the book is generally of interest because it supplies indirectly information as to the practice of surgery in a Parisian general hospital. The illustrations are remarkable because there are a number of clever sketches, with a ward orderly to represent the patient; the resident surgeon wears a skull-cap on the top of his head, and has a beard; masks and gloves seem out of fashion. The very young nurses have a fringe of hair protruding under their kerchiefs. Some of the drawings provoke a smile—for example, a nurse and orderly washing out the stomach, a man sitting on the side of his bed stark naked, feeding himself through a gastrostomy tube, and the vigorous methods of compressing arteries by the surgeon. Under general headings we find notes on the treatment of the complications following inhalation and spinal anaesthesia, artificial respiration being described under spinal anaesthesia by novocain. There follows a full account of the treatment of sepsis and haemorrhage. Under special headings, in which there are of necessity repetitions, we note that what is included mainly relates to the surgery practised on acute and urgent cases in a general hospital. The after-treatment of cases in special hospitals for eye cases and for children is not included; thus we miss accounts of the after-treatment following removal of tonsils and adenoids, of tracheotomy for diphtheria, and of the orthopaedic treatment of deformities. On the other hand, there is a full account of the after-treatment of gynaecological cases.

#### JUVENILE DELINQUENCY.

THOUGH there is now a tendency to regard the juvenile offender against the law as a patient to be treated rather than a criminal to be punished, the social mechanism for dealing with these cases is still very inadequate. As a contribution to this problem Dr. H. H. GODDARD's small volume on *Juvenile Delinquency*<sup>3</sup> will be found of practical value, because it contains an actual record of work accomplished and difficulties overcome. One of the great difficulties in coping with what is a very large social problem is to know the kind of organization necessary to deal with it at all adequately. The author shows that an attempt has been made by the legislature of the State of Ohio to deal seriously with the problem: a bureau of juvenile research has been established to treat cases appearing in the juvenile courts on scientific lines. The necessity for some such organization can be gauged from the fact that Dr. Goddard estimates that eventually the bureau, of which he is the director, will be called upon to handle 4,000 cases a year—cases of serious delinquency the causes of which must be discovered in order to prescribe treatment.

<sup>2</sup> *Thérapeutique Post-Opératoire à l'usage des chirurgiens, praticiens et infirmiers*. By E. Rochard and W. M. Stern. Paris: G. Doin. 1923. (Demy 8vo, pp. 723; 156 figures. Fr. 30.)  
<sup>3</sup> *Juvenile Delinquency*. By Henry Herbert Goddard, Director, Ohio Bureau of Juvenile Research. London: Keegan Paul, Trench, Trübner, and Co., Ltd. 1922. (Gr. 8vo, pp. 120. 3s. 6d. net.)

Broadly speaking, the author finds the juvenile delinquent either feeble-minded or what he characterizes as "psychopathic." His views as to the second group are not particularly encouraging or hopeful. He appears to regard the cases included in it as suffering from actual mental disease; and, somewhat unconvincedly, attributes this in a large proportion of cases to the influence of congenital syphilis. The term "psychopathic child" is not satisfactory; we should imagine that it must include a number of benign cases, due to unfavourable environment, neglect, and psychogenetic factors, in which a psychotherapeutic approach would be very beneficial.

### NOTES ON BOOKS.

THE thirty-ninth annual *Year Book of the Scientific and Learned Societies of Great Britain and Ireland*<sup>6</sup> is a well arranged volume which records the work done in science, literature, and art during the past year. The information which it gives cannot easily be found elsewhere, and the increasing size and scope of the volume make it each year more useful as a work of reference. Such a volume depends greatly upon the co-operation that exists between the officials of the numerous scientific and literary societies and the publishers, and both are, on the whole, to be congratulated on the results. The contents are grouped under sections, which include science generally—that is to say, those societies occupying themselves with several different branches of science, or with science and literature jointly: astronomy, mathematics, and physics; chemistry and photography; geography, geology, and mineralogy; biology; economic science and statistics; mechanical science and architecture; agriculture and horticulture; literature, history, and music; medicine; archaeology; and some others. Twenty-four pages seem hardly an adequate share for medicine in a scientific reference volume of 374 pages, but the fault may be rather with the secretaries of medical societies than with the editors of the *Year Book*. The personnel of the Ministry of Health is detailed, and the names are given of the principal officers of the British Medical Association, with the titles of the papers read at the different Sections of the Annual Meeting. The titles of all the papers read at the Royal Society of Medicine are included, and also the titles of the publications issued by the Medical Research Council and of the scientific papers published from the Lister Institute, together with similar details of many medical societies throughout the country.

The application to psychology in recent times of what in comparison with the older procedure by way of introspection may be called the observational and experimental methods has had the effect of greatly increasing public interest, and it is a sign of the times that a publication written so completely from the popular standpoint as the *Daily Mail Year Book* (1923) should contain an article on applied psychology. Within the limited space at his disposal Mr. W. N. Shansfield has succeeded in giving the casual reader a very good idea of what is being done with regard especially to applications of science to the estimation of industrial capacity, and of the intelligence and aptitude of children; in this connexion he relates the origin of the Binet-Simon tests, designed mainly to detect the cause of backwardness in any particular case. Dr. Kimmins, speaking from his experience in London schools in an address given during the annual conference of the Education Association last week, praised the Dalton plan for discovering the unusually endowed or unusually quickly learning child and giving scope to this ability or quickness, while not forgetting that the tortoise may win the race.

Professor HALLIBURTON's book, *The Essentials of Chemical Physiology* for the use of students,<sup>7</sup> was first published in 1893. New editions have been called for every three or four years, and we have now received a copy of the eleventh. It does not differ materially from the tenth, but new exercises have been introduced dealing with the detection of enzymes, the estimation of oxygen in the blood, and on gastric acid. Opportunity has been taken to rewrite the section on coagulation of blood: in concluding this section the author admits that he finds it difficult to be dogmatic and has been content to give an outline of what to his mind is the probable explanation of the remarkable phenomenon of coagulation. The exact part played by the platelets has still to be ascertained, but he thinks it not improbable that their function, if any, will be found in their effect upon surface action.

<sup>6</sup> *The Year Book of the Scientific and Learned Societies of Great Britain and Ireland*. Thirty-ninth issue. London: C. Griffin and Co., Ltd. 1922. (Demy 8vo, pp. vi + 374. 15s.)

<sup>7</sup> *The Essentials of Chemical Physiology*. For the Use of Students. By W. D. Halliburton, M.D., LL.D., F.R.S. Eleventh edition. London and New York: Longmans, Green, and Co. 1922. (Demy 8vo, pp. xi + 313; 71 figures. 1 plate. 8s. 6d. net.)

## DANGEROUS DRUGS ACT, 1920.

### THE POSITION OF DOCTORS AND DENTISTS.

THE following memorandum, dated January 9th, has been issued by the Home Office, and will subsequently be published in pamphlet form by the Stationery Office:

#### HOME OFFICE MEMORANDUM.

1. By the Dangerous Drugs Act and the Regulations made under it certain obligations in regard to the giving of prescriptions, keeping of records, etc., devolve on medical and dental practitioners and the Home Secretary, with whose Department rests the general responsibility for the administration of the Act and Regulations, has had under consideration the best means of carrying out such inspection as may be necessary from time to time to ensure the due fulfilment of those obligations. He has come to the conclusion that such inspection would be best carried out by medical officers, and after consultation with the Minister of Health and the Scottish Board of Health, it has been arranged that as a general rule this work shall be carried out in England and Wales by medical officers of the Ministry of Health, and in Scotland by medical officers of the Scottish Board of Health.

2. It is considered that it may be convenient for doctors and dentists to have a short statement of the main provisions of the Act and Regulations in which they are specially concerned.

#### I. GENERAL PROVISIONS.

##### Substances Involved.

3. The substances to which the Dangerous Drugs Act applies are: Raw opium; and

Collectively referred to as Dangerous Drugs:—

Medicinal opium;

Cocaine and ecgonine and their salts;

Morphine and its salts;

Diamorphine (heroin) and its salts; and any preparation, admixture, extract or other substance containing one-fifth per cent. or more of morphine or one-tenth per cent. or more of cocaine, ecgonine, or diamorphine.

The percentage in the case of morphine is calculated as in respect of anhydrous morphine.

4. No person is allowed to bring into, or take out of the country any of the drugs unless he is licensed by the Home Secretary, and no person is allowed to be in possession of the drugs (subject to the exceptions named in the next paragraph) unless he is licensed or otherwise authorized for the purpose, or unless the drug has been supplied for his use by a medical practitioner or in accordance with a medical or dental prescription.

##### Preparations Exempted.

5. It should be noted that the following preparations, though they come within the Act, are specially exempted from the Regulations and may be bought and sold in this country in the same way as ordinary "poisons" under the Poisons and Pharmacy Act:

Cereoli iodoformi et morphinae, B.P.C.

Emp. opii, B.P. 1898.

Lin. opii, B.P.

Lin. opii ammon., B.P.C.

Pasta arsenicalis, B.P.C.

Pil. hydrarg. c. opio, B.P.C.

Pil. ipec. c. scilla, B.P.

Pil. plumbi c. opio, B.P.

Pil. digit. et opii co., B.P.C.

Pil. hydrarg. c. creta et opii, B.P.C.

Pulv. cretae aromat. c. opio, B.P.

Pulv. ipecac. co., B.P. (Dover's powder).

Pulv. kino. co., B.P.

Sappos. plumbi co., B.P.

Tabletæ plumbi c. opio, B.P.C.

Ung. gallae c. opio, B.P.

Ung. gallae co., B.P.C.

It should also be noted that the following preparations do not come within the Dangerous Drugs Act:

Any preparation containing less than one-fifth per cent. of morphine or one-tenth per cent. of cocaine, ecgonine, or heroin. Thus any mixture containing in each drachm not more than 11 minims of tr. opii or 13 minims of liquor morph. use hydrochlor. and 15 minims of liquor morphinae acetat. would be unaffected by any of the provisions of the Regulations.

#### Medical Practitioners and Dentists are authorized Persons.

6. Any duly qualified medical practitioner and any registered dentist is authorized by the Regulations to be in possession of and to supply dangerous drugs and (in the case of medical practitioners only) raw opium, so far as is necessary for the practice of his profession. The words (in italics) are important: a doctor or dentist may not have or use the drugs for any other purpose than that of ministering to the strictly medical, or dental, needs of his patients.

7. Subsequently throughout this Memorandum "doctor" is to be read as meaning a medical practitioner whose name is on the *Medical Register*; and "dentist" as a dental practitioner whose name is on the *Dental Register*.

8. In what follows it should be noted that Part II applies to all practising doctors and dentists, Part III to those only that dispense.

## II. REGULATIONS APPLICABLE TO ALL DOCTORS.

*Prescriptions.*

9. The following remarks only apply to prescriptions for medicines containing a dangerous drug in sufficient strength to come within the Act (see above).

10. The Home Secretary has power to prescribe an official form to be used for such prescriptions, but he has not at present done so.

11. Under the Regulations the prescription—

(a) must be in writing and be dated;

(b) must be signed with the *full name* of the prescribing doctor or dentist (the Christian names, as well as the surname, must be written in full; initials do not satisfy the Regulations);

(c) must bear the *address* of the prescribing doctor or dentist (except in the case of prescriptions issued for National Health Insurance purposes on the official form);

(d) must state the name and address of the patient (a prescription may not be given for the use of the prescriber himself);

(e) must state the total amount of the drug to be supplied on the prescription.

12. Dentists may give prescriptions for dental treatment only, and in addition to complying with the above requirements they must mark the prescription "for local dental treatment only."

13. The prescription has to be retained by the chemist by whom it is dispensed (except in the case of prescriptions issued for National Health Insurance purposes on the official form), and he is only allowed to dispense it once, unless the doctor or dentist specially directs in the prescription that it may be dispensed twice or three times (but not more than three times) at intervals which he specifies. In no case is the chemist allowed to dispense it more than three times.

14. A doctor or dentist who gives, and a chemist who accepts and dispenses, a prescription not drawn up in every particular in accordance with these Regulations commits an offence against the Act.

15. The Home Secretary desires to impress as strongly as possible on doctors and dentists the importance of their observing these requirements strictly when giving a prescription. Any irregularity on the part of the doctor or dentist may lead to delay in the patient obtaining the medicine prescribed for him, and it is extremely unfair to the chemist that he should be placed in the position of delaying an important prescription, and possibly offending the doctor or dentist, or committing a breach of the law. The Secretary of State has reason to believe that at the present time there are very numerous irregularities in giving prescriptions for the drugs, and representations have been made to him by chemists as to the difficult position in which they are placed, and, he is afraid he must add, the annoyance or resentment displayed by doctors and dentists in many cases at being asked to correct the irregularities of their prescriptions.

*Method of Obtaining Supplies of the Drugs.*

16. A doctor or dentist who requires the drugs for the purpose of his practice may obtain them from any person who has a general licence or authority under the Dangerous Drugs Act to supply the drugs. All pharmacists who are lawfully keeping open shop in accordance with the provisions of the Pharmacy Acts are so authorized (except in the rare cases where the authorization has had to be withdrawn for offences against the Regulations), and all or practically all the established firms of wholesale chemists have also obtained licences from the Home Secretary to supply the drugs. In any case of doubt a doctor or dentist can always ascertain, by inquiry from the Home Office, whether a firm is authorized to supply the drugs or not.

17. It will assist the administration of the law, and probably also save the doctor or dentist some inconvenience, if he gives all orders for the drugs in writing (except in cases of extreme emergency), and signs them with his full name and address. The chemist has to satisfy himself before selling the drugs that the purchaser is authorized by the Regulations to have them, and in cases where the doctor or dentist is not well known to him some delay in making inquiries may be avoided by a full written order, duly signed.

18. If a messenger is sent by the doctor or dentist to take delivery of the drugs, the messenger must be given an authority in writing, signed by the doctor or dentist, to receive the drugs on behalf of the doctor or dentist; a chemist is forbidden to deliver drugs to a messenger not so authorized.

19. A doctor or dentist is not allowed to be supplied with the drugs on a prescription made out by himself in his own favour.

20. Doctors and dentists are advised to keep any dangerous drugs, when not in use, under lock and key so far as possible. This is not actually required by the Regulations, but is obviously a desirable precaution.

21. A doctor or dentist who requires the drugs solely for administration to his patients by himself personally, or under his own direct personal supervision, and does not dispense them, is under no obligation to keep the records required by the Regulations as explained in Part III of this Memorandum.

\* It is proposed in the case of prescriptions issued for National Health Insurance purposes on the official form to require only the surname in full, with the initials of the Christian names.

## III. REGULATIONS APPLICABLE TO DISPENSING DOCTORS.

22. Doctors who dispense or supply medicine\* are under the obligation to keep the registers of purchases and supplies described below.

*Register of Purchases.*

23. Separate registers or separate parts of a register are to be appropriated for each of the drugs. The form in which the register has to be kept is as follows:

Date on which supply received.	Name of person, body, or firm from whom obtained.	Address of person, body, or firm from whom obtained.	Amount obtained.	Form in which obtained.

24. The correct entry in the register must be made on the day on which the drug is received or the following day; an entry must not be cancelled, obliterated, or altered—any mistake must be corrected by a footnote or marginal note giving the correct particulars, and dated.

*Register of Supplies.*

25. Similar registers or parts of a register must be kept for each drug "supplied" in the following form:

Date of supply.	Name of person to whom supplied.	Address of person to whom supplied.	Authority of person, body, or firm to be in possession of the drug.	Amount supplied.	Form in which supplied.	Specify the ingredients of the prescription.

\* Where, as will usually be the case, the supply is on the doctor's own prescription, it will be sufficient to enter the word "Patient" in this column.

26. The entry must be made on the day on which the drug is supplied or the following day. The same rules as to mistakes and corrections apply.

27. *N.B.*—It is specially provided, however, by the Regulations, that if a doctor keeps a day-book in which he records particulars of any of the drugs dispensed by him to his patients, with the name and address of the patient and date of supply, he need only record in his register of supplies the date and the appropriate reference to the entry in his day-book.

28. A doctor who dispenses at more than one set of premises is required to keep a separate register or registers at each set of premises.

29. All records, including registers, day-books, and other documents, must be kept for not less than two years from the date of the document or the last entry therein.

## IV. OFFENCES AND PENALTIES.

30. A doctor or dentist who obtains, or attempts to obtain, the drugs for a purpose not covered by his authorization, or who infringes any of the Regulations, commits an offence against the Act, and if convicted is liable to a fine of £200 or to imprisonment with or without hard labour for six months, or to both, fine and imprisonment.

31. Further, the Home Secretary has power, after the conviction of any doctor or dentist, to withdraw from him his authorization; the effect of this would be to deprive him entirely of the right to be in possession of or to supply the drugs.

## V. HOSPITALS, ETC.

32. Hospitals, asylums, Poor Law institutions, or sanatoriums supported by a public authority or out of public funds, or by a charity or voluntary subscriptions, have been exempted by Home Office Order from the operation of the Dangerous Drugs Regulations subject to compliance with the conditions laid down in the Order. The terms of the Order (dated August 15th, 1921, and to be obtained from the Stationery Office) should be consulted.

## VI. INSPECTION.

33. All registers, and other records, required to be kept for the purposes of the Dangerous Drugs Act and Regulations thereunder, and any stocks of the drugs held, must at all times be available for inspection by any duly authorized inspector.

34. As indicated in the opening paragraph of this Memorandum, the Home Secretary has authorized Medical Officers of the Ministry of Health and of the Scottish Board of Health to act as Inspectors for this purpose in England and Wales and in Scotland respectively.

35. Notice of a visit for the purposes of inspection will not necessarily be given, and medical practitioners who dispense should make such arrangements that the registers and other records can be produced, if required, for inspection in their absence.

\* The obligation would apply in the case of a doctor or dentist leaving a supply of any of the drugs with a nurse for administration to a patient during the absence of the doctor or dentist.

# British Medical Journal.

SATURDAY, JANUARY 13TH, 1923.

## "ANGELS AND MINISTERS."

SIR JOHN SIMON, in his famous essay on a Ministry of Health, after putting his finger on the more glaring defects and wrongs of the sanitary condition of the country in 1854, indicated the obvious remedy: "Surely no one will doubt [he said] that this great subject should be dealt with by comprehensive and scientific legislation; and I hardly see how otherwise, than that it should be submitted in its entirety to some single department of the executive, as a sole charge; that there should be some tangible head responsible—not only for the enforcement of existing laws, such as they are or may become, but likewise for their progress from time to time to the level of contemporary science, for their completion where fragmentary, for their harmonization where discordant."

This was the ideal set before the General Board of Health by the great sanitarian who became its first medical officer. The establishment of that Board and the appointment of medical officers of health were largely due to the report of the Royal Commission appointed by Sir Robert Peel in 1843 at the instigation of Edwin Chadwick. Among those who gave evidence before the Royal Sanitary Commission of 1869 were Simon and Farr. "Speaking broadly," says Sir George Newman, "the 1843 Commission found the existence of a serious national evil of insanitation and ill health, and recommended a legislative remedy, whereas the 1869 Commission found that the remedy had proved ineffective, and recommended that 'the present fragmentary and confused sanitary legislation should be consolidated.' They proposed, in fact, for the first time, a Ministry of Health; but the case miscarried, and the Local Government Board was created in 1871."<sup>2</sup> But although the case did indeed miscarry, Simon throughout his long official career kept steadily before him the ideal expressed in his essay. He was convinced that there should be a Minister of Health sitting in Parliament, and that the duty of the central department of health should be, in the widest sense, to care for the physical interests of the people, just as their educational interests were the care of the Minister of Education: "the people, through its representatives, must be able to arraign him wherever human life is insufficiently cared for." Simon declared that the incongruities belonging to "our abortion of a sanitary system" must be ended, and he called for the appointment of a parliamentary leader (not necessarily himself a medical man) who could recognize principles and stick to them.

In 1868 the British Medical Association pressed upon the Government of that day the policy of instituting a Ministry of Health, and in subsequent years it again tried to obtain consideration of this national question, but without avail. Then, fifty years later, when the spirit of reconstruction was abroad, an opportunity came for furthering the cause. A feature of the closing stages of the great war was the movement of public opinion towards a demand for the extension and co-ordination of the health services of the country. In 1917 a Committee of the Association undertook the task of presenting to the Government and to the public the medical case for the establishment of a Ministry of Health, and a reasoned

statement was issued in the following April. The purpose of the proposed reform was to make administration more efficient through a combination of departments and co-ordination of powers. The Association's scheme for the new Ministry included the recommendation that an Advisory Council, composed of representatives of all the interests concerned, including the medical profession, should be, by statute, an integral part of the Ministry. This idea was further developed by Lord Dawson in his Cavendish lectures published in our columns on July 13th, 1918. A Medical Advisory Council, he held, should form part of the permanent organization of the Ministry. It is interesting to recall here the words of Simon sixty-four years earlier: "Into the hands of this new Minister—advised, perhaps, for such purposes by some permanent commission of skilled persons—would devolve the guardianship of public health against combined commercial interests, or incompetent administration."

The times were ripe for this reform. After preliminary administrative changes had been made a Ministry of Health was set up by Act of Parliament, and on July 1st, 1919, all the powers and duties of the Local Government Board and of the Insurance Commissioners for England and Wales passed to the Ministry of Health. Simultaneously a Scottish Board of Health and an Irish Public Health Council were constituted. The creation of the new Ministry carried with it an undertaking for reform of the Poor Law—as yet, however, unfulfilled. At that moment the Premier had a choice of two Cabinet colleagues of great administrative experience for the new post—Dr. Christopher Addison and Sir Auckland Geddes. Both were doctors of medicine, though each, in fact, was an anatomist, not a practitioner. Dr. Addison became first Minister of Health, with a great public servant, the late Sir Robert Morant, as permanent head of the department, and the first Medical Consultative Council was appointed by the Minister three months later, with Lord Dawson as Chairman. The new central department of health had much to contend against in its earlier months. The task set before it was tremendous. It was called upon to meet the demands of the medical profession and the public for better health conditions; at the same time it was ordered to find and apply an instant solution of the urgent housing problem. Within a year Dr. Addison had become an object of political enmity, and this campaign went on until April, 1921, when, being in disagreement with the Premier over the Government's housing policy, he resigned office to a layman. On the fall of Mr. Lloyd George's Government Sir Alfred Mond was succeeded by Sir Arthur Griffith-Boscawen, another layman, who at the moment is in the ambiguous position of being a Minister but not a member of either House.

This brief outline of events and opinions will perhaps be useful to the general medical reader as an introduction to Sir Lenthal Cheate's spirited article in the current issue of the *Nineteenth Century*. The essay is aptly entitled, "Ministers of Health—Defend Us!" Here we have in uncompromising terms the case against any layman ever holding the post of Minister of Health. In the interest of public health, says Sir Lenthal Cheate, this office must be held only by a medical man of recognized position in his profession, just as the Lord Chancellorship can be held only by a man of recognized position in the legal profession. The public and the medical profession, he declares, should not tolerate for a moment a Ministry directly concerned with public health being in the hands of a politician, however brilliant, who is not a doctor having special qualifications for the post. In making this point over and over again the author probably has in mind the saying, attributed to Delane, that repetition is the soul of journalism. He is aware of certain objections

<sup>1</sup> *Public Health Reports*. By John Simon, C.B., F.R.S. Edited by Edward Seaton, M.D. London, 1887. Vol. i.

<sup>2</sup> *An Outline of the Practice of Preventive Medicine*. 1919.

to the principle he advocates, but they do not dismay him. Thus the argument founded on the allegation that Dr. Addison was not a success is answered, and we think quite fairly, by saying that a Minister of Health should not have foisted upon him the conduct of political affairs that have no concern with public health, and in any case his failure in such matters should not be visited upon him as Minister of Health. "I can quite see that the Minister of Health should advise the Government to build more houses, and that he should be consulted as to whether the houses provided are sanitary and fit to live in; other than that function, I cannot see how the policy involved can possibly be a question for a Minister of Health. It is a great Government problem." Another objection—that several great departments of State are not represented by professional men in Parliament—is noted, but reserved for future argument.

Without going all the way with Sir Lenthal Cheate, we may say that his point of view, expressed with much cheerful vigour, has a great deal to commend it. The ideal Minister of Health would obviously be a medical man having the exceptional attainments here sketched. But entry into the House of Commons turns so largely upon the play of party politics, and the changes and chances of political life are so great, that when a Government has to be formed a medical statesman of the first magnitude may not be at hand. Such a man may be amongst us to-day; yet when he went out of office it might be said with truth: "Here was a Caesar! When comes such another?"

## A CENTURY OF PASTEUR.

PASTEUR was born at Dôle, in the Jura, on December 27th, 1822; he died on September 28th, 1895, at Villeneuve-l'Étang, where the French Government had assigned him a small estate for the study of rabies. His life of original research began in 1844, and into the next forty-five years was crowded so much that his pupil and successor Roux can truly exclaim, "When we study the work of Pasteur we marvel that one man could do so many things and such great things!"

Pasteur began with crystallography, and was one of the founders of stereo-chemistry; he went on to fermentation and founded the chemistry of the fermentation industries, now a big department of applied chemistry; and finally gave himself to the study of the cause of infectious diseases, and so founded the science of bacteriology, and laid down the main lines on which the study of attenuation and immunity has since proceeded. He had industry, patience, and courage, as well as genius; he had many fellow workers, not a few critics and opponents; these he met with the facts of experiment, brilliantly devised and logically interpreted, but for the most part he went his own way, gathering about him a great company of disciples, so that the *opus Pastorianum* did not end with his life.

It is interesting to note how Pasteur was drawn on from one set of investigations to the next. He was trained as a chemist, and for the first ten or twelve years of his working life was a lecturer on chemistry. His first great achievement was in physical chemistry.<sup>1</sup> Tartaric acid had been known since 1796. A substance which it was soon seen resembled it was found in grape-juice vats in Thann, in Alsace. To it the name racemic acid was given, and before long it was shown that it had the same empirical composition as tartaric acid. Biot, who was then at work on polarization, discovered that while tartaric acid, its salts and their solutions,

turned the plane of polarization of light to the right, racemic acid, and its salts and their solutions, did not produce any effect. Pasteur proved that the racemic salt consisted of two varieties of crystals, the one turning the plane of polarization to the right (dextro-rotatory tartaric acid), the other to the left (laevo-rotatory tartaric acid). The crystal of the one was the mirror image of the crystal of the other. He also showed that the two tartaric acids went into molecular combination, taking up a molecule of water to form racemic acid. In the product the two varieties of tartaric acid, active optically in opposite directions, produce optical inactivity. Here Pasteur was working at the foundations of stereo-chemistry, which in our days has gone on to the elucidation of the structure of the atom and of the molecule, as well as of the crystal. Pasteur in after life often expressed his regret that he had not stuck to crystallography; but the subject in all its bearings, it is now seen, could only be elucidated with the help of radium and the  $x$  rays. During the course of his investigations of racemic acid and its salts Pasteur made the surprising observation that when the green mould, *Penicillium glaucum*, was grown in a solution of racemic acid it attacked only the dextro-rotatory tartaric acid, leaving the laevo-rotatory variety untouched so long as any of the dextro variety remained. Thus did Pasteur get his first insight into the chemistry of life and the activities of the infinitely little. In 1854 Pasteur was appointed dean of the newly established Faculty of Science at Lille and a professor in that faculty. The town was the centre of the industry which makes alcohol from beetroot. He made the observation that the amylic alcohol produced during the process of fermentation consisted of two isomers, the one deflecting the plane of polarization and the other inactive; and the idea occurred to him that there might be some relation between the ferment and the molecular constitution of the bodies produced by the fermentation. He was diverted from these speculations by an appeal—to which all through his life he was always ready to respond—to come to the rescue of the industry. The request was made by a distiller, M. Bigo, who complained that the fermentation in some of his vats went wrong. Pasteur went to the distillery; in the healthy vats he found only the yeast, but in the sick vats he detected also small rods, which he proved to be living things.

His next observations were on lactic fermentation.<sup>2</sup> He had been transferred to an administrative post at the Ecole Normale, in Paris, and his experiments were made in an attic fitted up as a laboratory by himself, where he had no helper except his wife. He showed that the transformation of sugar into lactic acid was due to an organism hitherto undescribed, and he put out the idea that every fermentation was due to a ferment special to it, and that the ferment was a living microscopic thing. This was in 1857; in the following year he began to investigate the fermentation of sugar, which produces alcohol, and, besides that, as was then supposed, carbonic acid only. He found that in the process of fermentation small quantities of glycerin and succinic acid were produced, representing together about 5 per cent. of the sugar employed. He maintained that the fermentation was due to the life and growth of a living ferment—a commonplace to-day, but a view which at that time brought him into conflict with the general belief among chemists, which was that fermentation was set up by the disintegration of dying nitrogenous substances. He showed that, on the contrary, it ran parallel with the growth of the living ferment, and was in fact due to the activity of the living thing. At this stage he was brought

<sup>1</sup> Rev. des Deux Mondes, December 15th, 1922.

<sup>2</sup> Œuvres de Pasteur. Tome I. Dissymétrie moléculaire. Paris: Masson et Cie. (Fr.50.)

<sup>3</sup> Œuvres de Pasteur. Tome II. Fermentations et générations aérées spontanées. (Fr.65.)

into conflict also with those who defended the doctrine of spontaneous generation. We will not attempt to relate the prolonged controversy which ensued, but will only note that the arguments of his opponents stimulated Pasteur and his fellow workers, Roux and Chamberland, to perfect their methods of sterilization.

From lactic fermentation he passed to butyric, in which sugar and lactic acid are transformed into butyric acid, and made the unexpected discovery that the butyric fermentation was due to a micro-organism which could not live in contact with air. Very soon he established the existence of other anaerobic organisms, and reached the generalization that they were the true organisms of putrefaction, those which first attacked dead nitrogenous matter reducing it to simpler forms, which were then attacked by aerobic organisms which transformed them into still simpler bodies. Next he turned to the acetic fermentation: he was induced to do so by difficulties encountered in the manufacture of vinegar similar to those that had occurred in the manufacture of beetroot alcohol at Lille. French vinegar is made in butts half filled with wine and inoculated with the *Mycoderma aceti*, which grows on the surface as a sort of scum; failures in manufacture he showed were due to contamination of the wine with other microbes. This observation brought him into conflict with Liebig, who maintained that the organism was not present during the manufacture of vinegar in the German manner, from alcohol and sour beer. Everyone knows now that Pasteur was right. Next he was called upon to apply to wine the principles he had established with regard to the cause of failure in the manufacture of beetroot alcohol and of vinegar. He accepted an invitation from the town of Arbois, not far from his birthplace, to study the diseases of wine—acidity, bitterness, ropiness, and so on. By microscopic examination he proved that all were due to microbial contaminations, and that these germs could be destroyed by warming the wine out of contact with air to a temperature of 55°C., a process which did not interfere with subsequent maturation.

From wine, in 1870, he went on to beer, and by the application of the same principles rendered a similar service to that industry. Meanwhile he made his first contact with disease. In 1865 one of his old teachers, J. B. Dumas, appealed to his patriotism to investigate the disease of silkworms, which was ruining the silk industry. Rather against his will he accepted the invitation, mainly because he desired to help the unfortunate peasants whose livelihood was being destroyed. The disease was found to be associated with the presence of certain corpuscles which could be seen in the infected worms. These corpuscles were transmitted from the imago to the eggs. The inquiry was complicated by the fact that silkworms also suffer from another disease due to a sporing vibrio, but Pasteur showed how both diseases could be prevented, and his methods are now taught in special schools of sericulture. It was at this period of his life (1868) that Pasteur was struck down by left hemiplegia, but he recovered quickly, regaining all his mental and nearly all his physical activity.

Pasteur was disinclined to embark on the study of human diseases, but he consented, at the request of a pupil, to investigate the cause of puerperal fever. He came to the conclusion that it was due to a chain microbe (streptococcus), and that it was carried from the infected woman to a healthy woman by the doctor and the midwife. Consequently he recommended the sterilization of all linen and dressings. He had been watching also the work of Lister, and the great things it was achieving for surgery encouraged him to give his attention more and more to disease in animals and man. At the request of the French Director of Agriculture he

began to investigate anthrax, but first made some experiments on the disease called fowl cholera. It was during his study of the last-named disease that he discovered the possibility of attenuating the virulence of a virus. In this instance it was achieved by keeping the cultivation of the microbe at a temperature of 37°C., when it was observed gradually to lose its virulence. Birds inoculated with material taken from the cultures at a suitable period were protected from subsequent inoculation with a virulent virus. To this method of protection Pasteur applied the term "vaccination," in honour of Edward Jenner, who had, by another way it is true, formulated a method for protecting man against small-pox—a method Pasteur himself adopted when providing a means of vaccination against swine erysipelas. He turned next to rabies; the nature of the virus was then and is still unknown; but he recognized that the disease was mainly localized in the brain and spinal cord, and by drying the cords of rabbits at various periods obtained material for therapeutic inoculation. As Professor Ledingham has well said, "To Pasteur the accurate knowledge of a virus was simply a stimulus to attack the disease on the preventive side, but neither to him nor to his great contemporary Lister was this stimulus an essential one. If a virus could be demonstrated and cultivated outside the body, so much the better. Attenuation was all the simpler. So when he came to rabies, ignorance of the actual virus did not deter him from the attempt to attenuate its virulence."

There was in Pasteur something of the faith of the great religious propagandists. His religion was the love of humanity, and his observance was to win for man control over the forces of Nature; he would have agreed that "ignorance is the curse of God, knowledge the wing wherewith we fly to Heaven."

#### THE JENNER CENTENARY.

THE centenary of the death of Edward Jenner, the discoverer of vaccination, will be celebrated by the Royal Society of Medicine at a meeting on the anniversary day, Friday, January 26th. The President of the Society, Sir William Hale-White, will give an address on Jenner and his work, and a collection of relics and exhibits will be lent for the evening by the Wellcome Historical Medical Museum. The Curator of the Museum is arranging in it a commemorative exhibition of personal relics, pictures, engravings, drawings, documents, and caricatures, which will remain open for some months, and will be on view from 10 to 5 daily. The Curator asks us to say that he will be glad to hear from any persons possessing objects of interest in connexion with Jenner and his work which they would be willing to lend; loans while on exhibition will be insured, and any expense incurred in transit will be paid by the Museum. Communications should be addressed to Mr. C. J. S. Thompson, M.B.E., Curator, the Wellcome Historical Medical Museum, 54a, Wigmore Street, London, W.1. As already announced, the Académie de Médecine intends to celebrate the centenary on January 23rd; the Académie has invited the Royal Society of Medicine to send representatives, and is ready also to welcome any Fellows of the Society who may be able to go to Paris.

#### THE HOUSING OF AN X-RAY DEPARTMENT.

THE new x-ray department of the Manchester Royal Infirmary, some description of which appeared in the JOURNAL of November 25th, 1922 (p. 1044), was the principal subject of a lecture given by Dr. A. E. Barclay before the Röntgen Society on January 2nd. The planning of an x-ray department is usually a matter of compromise and to some extent of makeshift, but at Manchester this factor of compromise had required less consideration than usual, except in so far

\* Pasteur Supplement to Nature, December 23rd, 1922.

that the department had to be accommodated within the walls of an existing building of mediaeval solidity and modern ferro-concrete construction, originally designed as common rooms for students. One interesting feature was the method adopted for protecting the partition walls between the various rooms. It had been intended to protect them with sheet lead, but the suggestion was made that commercial barium sulphate could be used with cement, and after a number of experiments a successful mixture was found. When tested with radium a thickness of three-quarters of an inch (19 mm.) of this plaster proved to be equivalent to between 3.5 and 4.5 mm. of lead. The walls of the treatment cubicles were plastered on both sides, the total thickness of plaster being one and a half inches. The ease of application and the smallness of cost of the barium plaster should make this the protective method of choice. The cost of lead at the time the department made its purchases was £22 a ton, while commercial barium sulphate was obtained at £10 a ton. In discussing the general question of housing an x-ray department, Dr. Barclay said that in the average country hospital, if one looked for the darkest, steepest, and most awkward stairway leading below ground, one generally found that it led to the x-ray room. In one English town a hospital of 60 or 80 beds had enlarged itself by absorbing the adjoining police station. The police had sold the place because the cells were too damp for the well-being of their lodgers, and it was in two of these cells that the x-ray and dark rooms were accommodated. An x-ray department in a cottage hospital was expected to tackle anything and everything; hence the outfit in the small hospital had to perform many functions, though, the number of cases being small, there was usually plenty of time for the necessary rearrangement. In a general hospital of 150 beds both radiographic work and x-ray treatment would be in progress for the greater part of the day, with the result that separate rooms would be necessary for these two branches. In a still larger hospital there would be further subdivisions, such as a special room for screening work. In a hospital associated with a medical school a new set of conditions presented themselves; here the large volume of routine work of a general hospital had to be done, and in addition much special work along the lines of teaching, investigating, and recording. Dr. Barclay's plan for a large hospital with a teaching school included the provision of rooms both for ordinary and for intensive x-ray treatment, an ordinary radiographic room and a special room for screening, a fluoroscopic room for serial plates and the like, and a suite of rooms for the medical officers and nurses, and for office, storage, and workshop purposes. The staff should include two senior and two junior medical officers, a physicist, three assistants for x-ray treatment, a radiographer, a photographer to develop negatives, a photographic librarian, a mechanic, a clerk, two nurses, and a sister. The largest department differed from the small department in the cottage hospital only in the respect that the numbers dealt with made it necessary to multiply the units, and as the units were multiplied it was reasonable to adapt certain of them to certain special types of work. In small hospitals radiology was a problem which even apart from the cost was not easy to solve owing to the difficulty of obtaining the services of a radiologist; they could not afford to pay a radiological specialist adequately for the time that was necessary, and from his colleagues on the staff such a specialist was not likely to get sufficient private work to make the post worth his while. The only solution appeared to be the provision of central x-ray clinics, maintained by a number of small hospitals, each of which would contribute according to the amount of work it required to be done. In each small hospital there would be, in addition, a simple plant for dealing with fractures and light work, which would be operated by one of the assistants, who would bring the plates back to the centre for development and report. The central clinic would also be available for x-ray work under national insurance when that scheme came to provide specialist services. Doubtless such clinics would pay their way and afford adequate salaries for radiologists, but they

would be abused by people who could afford to pay full fees and would be harmful to the interests of the radiologist who depended on private practice.

#### VITAMINS AND REPRODUCTION.

THE existence of the three vitamins A, B, and C has been generally accepted, but several workers have brought forward evidence for the existence of other vitamins. For example, it has been suggested that the antirachitic substance present in cod-liver oil is not identical with the fat soluble vitamin A. It is not improbable that there are a large number of organic substances, small supplies of which are essential to animal life, and hence it is not possible to set a limit to the number of these substances. The existence of a new vitamin essential for reproduction is suggested by H. M. Evans and K. S. Bishop of the University of California.<sup>1</sup> The authors fed rats on a diet containing a limited amount of vitamin A, plenty of vitamin B, and no vitamin C; on this diet the rats grew and developed normally but did not reproduce. The addition of lettuce leaves or even of dried alfalfa grass to the diet was followed by sudden restoration of fertility; the same effect was produced by an excess of butter, but not by cod-liver oil nor by orange juice. It is difficult to express an opinion on this work. It has long been known that animals on a diet slightly deficient in vitamin A will grow but will not reproduce. It is extremely difficult to be certain that the variations in reproduction observed were due to the action of a vitamin hitherto unknown and not to variations in the quantity of vitamin A in the diet. That this may be the explanation is made the more likely by the fact that the authors used butter and milk fat as the source of their vitamin A, and tenfold variations of vitamin A content have been observed in different samples of milk and butter. The number of possible experimental errors in work upon vitamins is extremely large, and hence it is permissible to reserve judgement as to the value of the conclusions reached by Drs. Evans and Bishop until we have an opportunity of studying their experimental methods in more detail. If the existence of a specific substance stimulating reproduction is established the observation may be important for the treatment of sterility both in the human race and in stock.

#### THE RETREAT, YORK.

THE 125th annual report of the Retreat, York, for the year 1921, records the retirement of Dr. Bedford Pierce, who had been its chief medical superintendent for nearly thirty years. The Committee of Management expresses its appreciation of the work done by Dr. Pierce during his long term of office, and records that under his management the great traditions of the Retreat have been more than maintained, and its sphere of usefulness extended. Dr. Pierce alludes to some of the changes which have taken place, and describes more particularly the efforts which have been made to develop the profession of mental nursing. Apart from the ordinary courses of instruction given in the hospital Dr. Pierce has arranged an annual lecture for the nursing staff. These lectures have been delivered by well known psychiatrists, and if it were possible to publish them in book form they would no doubt be found of value to mental nurses as a whole, and would usefully supplement the systematic knowledge contained in the nursing manuals. The report contains some interesting comments on the practical difficulties met with in dealing with voluntary boarders in mental hospitals. The question of certification which sometimes arises in these cases is recognized to be one of considerable difficulty. As Dr. Pierce points out, it is obviously not straightforward to receive a patient on the understanding that he may leave when he wishes, and then directly he asks to go to make arrangements for his detention as a certified patient. At the same time, though the practice of certifying voluntary boarders whilst in residence

<sup>1</sup> On the Existence of a Hitherto Unrecognized Dietary Factor Essential for Reproduction. *Science*, N.S., vol. lvi, No. 1458, December 8th, 1922, p. 651.

may be undesirable, it cannot always be avoided. A change of phase in the psychosis may occur in which the voluntary status of the patient becomes impossible, and Dr. Pierce gives some striking instances in which certification became necessary in some of his voluntary boarders. There is no doubt that the addition of voluntary cases adds to the problems of the medical superintendent, and renders him liable to criticism even when he has acted in the best interests of his patients. Since, however, the system by which patients can be admitted on a voluntary basis to mental hospitals has much to commend it, every effort should be made to ensure that it is carried out in the right spirit. As Dr. Pierce observes, if either patients or boarders have any grounds for thinking that voluntary admission was intended to facilitate subsequent certification—in other words, that the authorities were insincere in accepting them—it would certainly cause grave injury to the prestige of the hospital. He suggests, also, that if any individual patient should feel aggrieved on this matter, even without justification, it is desirable that he should not remain, but be transferred elsewhere. Lastly, we may note that the committee has established a nursing home (Millfield), quite apart from and independent of the Retreat, for the care and treatment of mild and incipient cases of nervous disorder. Notwithstanding the financial difficulties it entails, the committee feels it right to continue this venture in response to the urgent public need for a home of the kind, free from any institutional connexion or association. This progressive move should meet with success: it represents on a small scale what it is hoped may be possible in the future in connexion with the public mental hospitals.

#### A SCOTTISH MEDICAL SOCIETY.

THE Aberdeen Medical Society was founded in 1789 by James McGrigor, afterwards known to fame as Sir James McGrigor, Bt., K.C.B., F.R.S., and for thirty-five years Director-General of the Medical Department of the Army. With him were associated James Robertson and a few medical students. In 1812 the society was reconstructed under the name of the Aberdeen Medico-Chirurgical Society, with William Livingstone, M.D., as president. Eight years later it entered into occupation of its permanent home, the hall in King Street, designed on classical lines by Archibald Simpson. Throughout the 133 years of its existence the society has had close relationships with the Aberdeen Royal Infirmary and with the Aberdeen Medical School. In its early days it did much to improve the medical teaching in the two rival foundations—King's College and Marischal College—which in later times amalgamated to form the University of Aberdeen of our own day. All this and much besides is told with pious care by Dr. John Scott Riddell in the *Records of the Aberdeen Medico-Chirurgical Society*.<sup>1</sup> Drafted at first in the form of a presidential address, the historian's work grew as he dug deeper into the records of the past, until its size got beyond the possibility of oral delivery at one session. The material was thereupon recast, many additions were made, and the whole was arranged for publication in book form. In this process the record of the work and influence of the Aberdeen Medico-Chirurgical Society came to embrace the medical history of Aberdeen since 1789. And so, as the author says in his peroration (chapter xii), "What was begun as a short address has expanded into a little book." A shortened version was, however, spoken to the members in the Society's Hall, by Dr. Scott Riddell, on October 26th, 1922, that being the statutory day for the delivery of the presidential address. At the conclusion of the address a copy of the book now before us was handed to each member. It is a pleasant volume to read and to handle; the printing is good, and the eleven illustrations, including several portraits and views of old King's College and Marischal College, are well reproduced on art paper.

#### HICCUP.

THOUGH it can be a grave complication in surgical shock and is then justly dreaded by surgeons, hiccup is usually a disorder which, though distressing to the sufferer, is regarded with a very moderate degree of sympathy by the onlookers. It may, however, go on for hours and days, and seriously interfere, not only with the comfort, but even the health of the subject. There are a multitude of remedies, some of them really partaking of the nature of folklore, but their action is capricious. Master John Arderne had evidently met with troublesome cases, for he has a note on remedies "against hiccough." He writes: "Let the leech tell the patient to hold his breath as long as possible. But if this does not stop the hiccough make him vomit, with radishes and mastiche. Let him drink warm water with a decoction of dill. Rue, too, drunk with wine is useful in such cases." A correspondent has sent us an extract from the Rev. W. B. Money's book, *Humours of a Parish and other Quaintnesses*, published a couple of years ago. Mr. Money's remedy presents some resemblance to Arderne's first prescription, and though the feat is not quite easy to perform it seems unlikely that it can have any injurious effect. "Take a tumbler and fill it about half-full of water, put your lips to the opposite side of the rim to what you ordinarily would in drinking, tilt the glass away from you instead of towards you, and so sip the water. That is all, but you will want nothing more; you will be a healed, a quiet, a restful man." Mr. Money declared that he had never known it fail, but relates the following instance as its greatest triumph: "I was fishing off the coast of Cornwall and my fisherman was fiercely attacked by hiccups, which he called 'the jicks.' They had lasted for two days. They were of the most terribly noisy character. They were almost like the 'minute gun at sea.' Poor fellow, they kept him awake at night. He really was in a most parlous condition, but he snuffed at my remedy and I couldn't induce him to try it till the end of the second day. When he did try it he was cured directly. The storm of hiccups was hushed, and now he is the most devoted believer in its powers." Mr. Money's prescription seems to be nothing but an ingenious device for inducing the patient to keep his lungs for a time in an average condition of distension, though he can still breathe. Ever since the classical experiments of Hering and Breuer we have known that on distension of the lungs afferent nerve ending of the vagus are excited and the corresponding impulses on reaching the respiratory centre inhibit inspiration. It seems, therefore, that these impulses inhibit also the violent inspiratory spasms of hiccup, and that the temporary relief thus produced lasts on for at any rate a very considerable time, so that the hiccup can by this means be controlled. Master Arderne's prescription of holding a deep breath for as long as possible seems to depend on the same principle.

#### MILK AND CREAM REGULATIONS.

IN 1912 Regulations were made under an Order of the Local Government Board the object of which was to prevent the use of preservatives in milk and to restrict their use in cream. Amending Regulations made in 1917 limited the amount of boric acid which could be added to cream to an amount not exceeding 0.4 per cent. of the cream, and required that on the labels attached to the vessels containing the cream there should be printed "Not suitable for infants or invalids," in addition to the words "Preserved cream." Early in January, 1921, the Minister of Health issued a memorandum with regard to the reports of public analysts under the Sale of Food and Drugs Acts, and the reports of medical officers of health on the Milk and Cream Regulations, and in a circular recently addressed by the Minister to town clerks and the clerks of county and borough councils a request is made that the reports for 1922 of these two officials should be on the lines of that memorandum. Information is asked for as to the results of proceedings taken with respect to samples examined and found not to be genuine, as to the extent to which preservatives are added

<sup>1</sup> *The Records of the Aberdeen Medico-Chirurgical Society from 1789 to 1922*. With Recommendations and Reflections. By E. M.A., C.M., LL.D., President of the Society. 1922. (Demy 8vo, pp. xii+144; 6d. cloth.)

to food, and in the case of samples of milk as to the number of instances in which a sample of milk is reported on adversely and a further sample is taken direct from the cow for comparison. The medical officer of health is asked to supplement his report on the administration of the Milk and Cream Regulations with information as to the action taken under Section 4 of the Milk and Dairies (Amendment) Act, 1922. This is an important section, for it prohibits the addition to milk of any colouring matter or water or of any dried or condensed milk or any skimmed milk or separated milk. If the section is thoroughly and completely enforced an end ought to be put to the sophistication of milk which it is to be feared prevails in some districts.

#### THE JUBILEE OF THE ROYAL NORMAL COLLEGE FOR THE BLIND.

THE Royal Normal College for the Blind at Norwood is about to celebrate its jubilee, and its treasurer, Lord Burnham, is making an appeal for help to mark the event by establishing its finances upon a surer foundation; he asks for £75,000. There are few institutions for the training of the blind which are better known, and certainly there is no other that has done better work. The late Sir Francis J. Campbell, who was for many years the organizer and head of the college, had a genius for efficient management, and his ideas of what a college for the blind should be were far in advance of his time. Those ideas have been largely realized at Norwood both in his own time and subsequently under the control of his son, Mr. Guy M. Campbell. The work of the college is essentially practical, as will be apparent to anyone who pays a visit to the institution. The schools for the teaching of pianoforte repair and tuning are unique, and the efficiency of the training which is given to the blind who show musical capacity, either as performers or pianoforte tuners, is most excellent. The work is not limited to this branch, but extends to all that is required for an efficient higher training of the blind. The writer of this annotation visited the college recently and was greatly impressed with the excellence of the work in progress, and with the industry shown by both teachers and pupils. There was also a remarkable spirit of comradeship which is of inestimable value in replacing the shrinking timidity of the blind by a spirit of assurance and independence. The appeal of the college is one that should be supported by the generous-minded.

#### PHYSICAL TRAINING IN ELEMENTARY SCHOOLS.

IN 1917 the Board of Education offered grants in aid of the salaries of "organizers" of physical training in order to secure a high level of efficiency amongst the school teachers who were themselves to carry out the necessary physical exercises of the children. The organizers were not to teach the children, but to instruct and stimulate the teachers in this work, which was to be regarded as part of the regular curriculum. In a new circular (No. 1291) issued recently the Board states that experience has shown that the school teachers are competent to undertake this work, and that they can derive great benefit from the advice and demonstrations which the organizers are able to give. Certain education authorities have arranged for the organizer to engage in the actual teaching of the children, but this the Board finds unsatisfactory; the organizer becomes an expensive supernumerary, and the work which should be integral with the school work becomes a side issue in which the teachers are not directly interested. Other authorities have delegated certain teachers to do the work, with similar disadvantages. Yet other authorities have appointed persons to these duties without obtaining recognition for them as organizers. The Board states that it has no wish to close the door to reasonable experiments, which it will consider on their merits, but generally speaking it adheres to the practical advantages of its own scheme. The expenditure involved is small, and it is anticipated that the advantages to the children of the plan

if properly developed will gradually afford relief from some of the heavy expenditure on other "special services." The advantages of the physical training as a means of preventing debility and promoting health, and also its general educational value in cultivating habits of discipline, self-control, and a sense of order and responsibility, need not be insisted on.

#### HOOKWORM DISEASE IN INDIA.

THE results of an investigation into the distribution and control of hookworm disease in India, prepared by the International Health Board of the Rockefeller Foundation, New York, have been published in the *Indian Journal of Medical Research* (October, 1922). The disease is present over almost the whole of the Indian Empire, but is more prevalent in Bengal, Assam, and Madras than in other districts. Of over 100,000 annual emigrants from Southern India arriving in Ceylon, the Malay States, and British Guiana, about 70 per cent., and among immigrants from India arriving in the United States from 63 to 90 per cent., were infested. In the Madras Presidency it is estimated that 70 per cent. of the population of 45 millions are infested, and many of these fall an easy prey to tuberculosis and other diseases. The infestation rate is high among English troops, and of the Indians of the Mesopotamia Expeditionary Force 24 per cent. were affected. Although in 1888 the prevalence of the disease was known and it was recognized that the consequences might be serious little was done until 1903; since then its importance from the economic point of view has been recognized by the establishment of treatment stations and by the inauguration of educational campaigns explaining the importance of early treatment and the value of preventive measures. As regards the distribution of the species of parasite, *Necator americanus* appears to occur in Southern India, and the *Ankylostomum duodenale* in Northern India. The damp heat of the Indian coal mines is favourable to larval development, and infestation is found among the coal miners in the Madras Presidency and also in the gold miners of Mysore; it is thought probable that as the workings in the coalfields become deeper the disease will increase. Although no organized effort is made by the Government for the control and eventual eradication of the disease, the Indian Medical Service is alive to the seriousness of the problem, and is endeavouring to estimate its relative importance as a factor in the ill health of the people. Specific methods of control, which have been found to reduce the number of persons suffering from hookworm disease and the consequent anaemia, consist in the examination of the tongue and conjunctivae of the workers at least once every three months, and the administration of iron twice daily and of beta-naphthol once a month. Where this plan has been effectively carried out the labour efficiency of the coolies has, it is estimated, been increased by 25 to 50 per cent., and it is believed that what has already been accomplished in 30,000 persons with a minimum of friction could be done for the whole 300 millions. In addition to the benefits so attained, such control of disease might be expected materially to assist in the abatement of other diseases, such as cholera and plague, by overcoming prejudices against more extensive sanitary programmes. Suggestions are outlined in the article for educational campaigns, and, with Government assistance, for the building and management of latrines, for the improvement of water supply and surface drainage, and for the care of the general health.

THE Hunterian Oration before the Royal College of Surgeons of England will be delivered by Sir John Bland-Sutton on Wednesday, February 14th, at 4 p.m. The President and Council have issued invitations to a dinner in the College on the evening of the same day.

THE usual half-yearly indexes to the *JOURNAL* and to the *SUPPLEMENT* and *EPITOME* have been prepared. Any member or subscriber wishing to have one or all of the current indexes can obtain them post free on application to the Financial Secretary, 429, Strand, W.C.2.

# NINETY-FIRST ANNUAL MEETING of the British Medical Association, PORTSMOUTH, 1923.

The Golden Barque, the weather vane on St. Thomas's Church tower.  
Length of hull, 3 ft. 5 in.

THE ninety-first Annual Meeting of the British Medical Association will be held at Portsmouth next summer under the Presidency of Mr. Charles P. Childe, F.R.C.S., Senior Surgeon to the Royal Portsmouth Hospital, who will deliver his Address to the Association on the evening of Tuesday, July 24th. The sectional sessions will be held on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th, the scientific and clinical work of the Annual Meeting being divided among sixteen Sections, as follows: Medicine, Surgery, Obstetrics and Gynaecology, Pathology and Bacteriology, Neurology and Psychological Medicine, Ophthalmology, Public Health, Diseases of Children, Laryngology and Otology, Radiology, Naval and Military Hygiene, Tuberculosis, Medical Sociology, Orthopaedics, Venereal Diseases, and Anaesthetics. The full list of the names of

officers and the provisional programme for the sectional discussions and demonstrations will be published in due course in the SUPPLEMENT. The Annual Representative Meeting for the transaction of the medico-political business will begin on the previous Friday, July 20th, at 10 a.m. Saturday, July 28th, the last day of the meeting, will be set apart for excursions to places of interest in the neighbourhood. The article published below is the second of a series of descriptive and historical notes on Portsmouth and its surroundings, for which our readers are indebted to Dr. W. Carling, Chairman of the local Printing Committee; the introductory article appeared in the JOURNAL of December 9th, 1922 (p. 1137). The Honorary Local General Secretary for the Portsmouth meeting is Mr. C. A. Scott Ridout, F.R.C.S. (St. Elmo, Clarendon Road, Southsea).

## AN OUTLINE OF PORTSMOUTH HISTORY.

### I. PORT DOCK AND HARBOUR.

"Would you lift the veil, long fallen, on the Ages rolled away  
And sealed as a Past Forgotten? Who knows but perchance ye may  
If ye go as little Children, and dream on the upland sward,  
But they pass no doubting cynic where the Gods keep watch and ward."

Mr. H. G. Wells, the writer of many thought-provoking books, once lived on Portsea Island. Before he became an author he worked and lived in one of Portsmouth's emporiums. He, in the imagination of one of his created characters, came after a dusty journey and rested on the side of Portsdown Hill. He philosophized and enjoyed the not unpleasing picture of the Solent tinted with the rays of the setting sun. He, like many another Portsmouthian has done and will do again in the future, powdered how and why Portsmouth should have been built on that mudflat island and not on the protected and sunny side of Portsdown. Indeed, quite recently Portsmouth did extend her boundaries, and has included Portsdown within her borough jurisdiction. In fact, new houses are beginning to dot the sunny face of the down. Sitting up here against the thyme-scented short grass on the chalk, one sees the Wight standing clear in the sea. Below at the foot of the down is a stretch of flat land intersected here and there by water channels, bays, and harbours, and between the flats and the Wight a narrow channel of the sea—the silvery Solent. Here, contemplating the harbour and its creeks, one is struck by its sheltered position and the many places a vessel could rest in without being seen. Hills to the north, and at the south a narrow entrance, easily defended if need be, opening from a sheltered strait protected from the storms of the channel by the Wight.

Should the visitor have with him a map of England he will on looking at it soon be struck with another fact. The coastline is much broken up and there are many places where the arms of the sea run a long way inland. Now let him take a blade of grass, if he has nothing else, and cut it according to the scale of his map to measure seventy-five miles. Place the scale anywhere on the map, one end on the seacoast, and he will find there is scarcely a town or village not reached by the other end. In the days when there were no aeroplanes, no motor lorries, no railway trains, methods of transport were indeed cumbersome and slow on land. It was then the day of the small ship, towns near and on the coast were able to exchange their marketable goods by water transport. Thus all round the coast, wherever there was a convenient or natural anchorage, there we have a town and port. Harbours were essential for the growth of the country.

Most towns have grown up round some hallowed spot sacred to history or romance, round some aerie castle, revered shrine or well, round some stately manor house with its family traditions of chivalry and statesmanship, round some spot of beauty or utility. Portsmouth grew up round its harbour. The land-locked harbour we have been watching

from the hill called Portsmouth into being, and Portsmouth itself called into being its docks, its fortresses, its castle and its hospice, and its sunny Southsea.

Ever since his appearance on this globe man has been a wanderer; his face is ever set towards the west, and the British Isles come right in the track to the setting sun. Palaeolithic man was here when it was possible to cross from France on dry land. His flint implements have been found on Southsea Common. He did not found Portsmouth, neither did the Neolithic man who followed him, bringing his beautifully wrought and polished stone and bone artefacts. The men of Bronze may have come this way, landing at the top of the harbour, for they have left their earthworks or rings, their long barrows and their round barrows, scattered over Hampshire and Wiltshire. The westward thrust, started by the drift of population, next brought to these isles from Europe two tribes of Celts or iron-using peoples. One has been distinguished as Gaelic (and their descendants may perhaps be found to this day in Ireland and Scotland) and the other as Brythons. The second race had learned on the Continent to smelt iron and to build boats. Their boats were swift and were used as models by the Romans when they came. The sails were dyed blue, probably for the same reason that a modern ship is painted slate colour. The Brythons were later joined by a tribe closely related to them—the Belgae. The latter were very famous for their iron work, and were at one time strongly established on the site that is now occupied by the city of Winchester.

The inhabitants of Britain were a highly civilized people when Caesar appeared amongst them. They had regularly planned towns and villages, agriculture was developed, the crafts of weaving, pottery making, and metal working were practised. For warfare they had chariots and horses, they used metal coins for barter, and they had an overseas trade through Phoenician mariners.

Ships when first built must of necessity have been small in size, and neither could they for many reasons be at sea for any length of time, nor could they go far from the sight of land. Consequently it would be quite natural for them to hug the shore and be on the lookout for estuaries, creeks, natural harbours, and protected waterways. Now, where could these creek-seeking men find a better place than the protected waters of the Solent or a more convenient harbour than that between the mainland and the Isle of Portsea—a narrow entrance easily watched and if need be protected; with waters broadening out and many creeks and bends in which to hide; plenty of soft mud banks on which to run the boats for repair and rest, and the chalk hills on the north preventing any sudden invasion from the mainland? Here at the north-west corner of the harbour the Britons had a town and a landing place, and here on the same spot the Romans established the westernmost station of the "Litus Saxonicum." Thus for 2,000 years of historic time has Portsmouth harbour been a centre of naval and maritime activity. Roman Porchester was a castle enclosing an area of 9 acres, and its walls, as measured to-day, are 10 feet thick.

After the Roman departure Saxons and Jutes landed at Porchester, and have left their marks behind all along the Meon Valley. The *Anglo Saxon Chronicle* records a legend that in A.D. 501 "Port and his two sons, Beida and Maegla, came into Britain with two ships at a place called Ports Mutha." Whether this story be true or no, there is plenty of evidence of Saxon occupation in the neighbourhood. The record follows the account of the landing in 495 of Ceauric, who became the first King of the West Saxons.

In 860 Danes landed at Southampten, near Porchester, established themselves on shore, and proceeded to Winchester and took the city. Alfred was now king, and he to the con-

clusion that the Danes must be met on the sea; he therefore turned his mind to ship building and ship designing. In 893 "he gave orders for building against the Esks long ships, which were full nigh twice as long as the others. Some had sixty oars, some more; they were not shaped after the Frisian model, but so as he himself thought they might be most serviceable." This is interesting as the first indication of a British navy. Most of the fighting was done off the Hampshire coast, and a few years ago the remains of a Danish ship, 30 feet long, was found near here up the Hamble River.

Our next invaders were the Normans, who when their conquest was complete built a castle at Porchester on the Roman site. The Norman invasion was different in character and purpose from those that had taken place before. This was an extension of the Norman kingdom. William came with the titles of Duke of Normandy and Aquitaine, Earl of Anjou, and added to his royal roll that of King of England. The Norman kingdom was now divided and separated by the English Channel. The king would require knowledge of all parts of his kingdom. It would be necessary, therefore, for ships to cross the channel.

Opposite nearly to the Isle of Wight were the ports of Bawlfleur and Honfleur. What more natural than that ships from these ports should make for the sheltered waters of the Solent. In fact, for the crossings of the early Norman kings of England first Southampton, then Porchester, and finally Portsmouth became the port of embarkation. From 1066 to 1204 Hampshire was the heart of the Norman kingdom.

Domesday Book makes no mention of Portsmouth nor of Portsea Island, but speaks of Bedhampton, Wymering, Cosham, Bouthaut, Porchester, Buckland, Copnor, and Fratton as making up the "Hundred of Portsdown." The last three manors mentioned are situated on the Isle of Portsea, and now form part of the borough of Portsmouth. Buckland was held by Hugh de Port, who held fifty-five other manors in this country direct from the Crown, besides some others indirectly. In 1085 there may have been a few fisher folk living at the south-west corner of Portsea Island; a hundred years later there were enough people living here to justify their demanding a charter. This increase was undoubtedly due to

the coming and going of the Norman kings.

With the Norman restoration of Porchester the harbour again became important. On returning from the first Crusade Robert Duke of Normandy found his youngest brother had seized the throne. Robert gathered his forces about him and landed on the shores of Portsmouth Harbour in 1101. At West Meon he met his brother, and arranged a peace which left Henry in possession of the throne. Henry was now a frequent visitor via Winchester, Bishop's Waltham, and Wickham to Portsmouth Harbour. The *Chronicle* tells of his taking ship here in October, 1114, and again at Whitsun, 1123. On this latter occasion he stayed on board a ship for a week awaiting fine weather in order to cross the channel. This was probably a matter of great importance to Portsmouth. The narrow entrance to the harbour, the wide expanse of land-locked water—calm within, rough without—must have impressed on the minds of the travellers a great feeling of security. The king, too, would remember that only a few years before his brother had landed here without opposition. The old castle being restored, Henry I in 1133 founded here the Priory of St. Mary at Porchester for Canons Regular of the Order of St. Augustine, "for the benefit of the souls of his Father and Mother, and William (Rufus) his brother, his ancestors and successors, and for the prosperity and safety of his kingdom." Forty years later, for some unknown reason, the Priory migrated to Southwick, on the other side of Portsdown Hill. All that now remains of the Priory buildings is

West doorway, Porchester Church.

the beautiful church of St. Mary. The west front has a fine decorated Norman doorway similar to that at Iffley. Like the Oxford gateway, it has a sculptured figure of Sagittarius, and as this figure occurs in the badge of Stephen it may be that the church was completed in his reign. The font is a richly carved specimen of Early Norman work.

The commencement of the civil wars in Stephen's reign began with the landing of Matilda on the shores of Portsmouth Harbour.

It is recorded that Henry II crossed from and returned to Portsmouth Harbour at least ten times. In 1177 he ordered most of the shipping of England and Normandy to assemble here to transport an army to Bauffeur.

Richard Cœur de Lion was in France when his father died. He returned to England via Portsmouth and immediately set to work to organize his crusade. On returning from Palestine he was detained a prisoner through the treachery of the King of France. Eventually, on reaching England he held a conference with his barons at Bishop's Waltham and immediately set to work to gather an army and fleet together in Portsmouth Harbour to avenge the insult. Whilst these preparations were in progress he was compelled to remain some time in the little town of Portsmouth, and it is reported of him that he passed the time superintending the erection of a hall with a kitchen and private apartment for himself. The spot chosen for the royal residence is now covered by the Clarence Barracks. Richard not only built for himself but granted sites to his followers on which they could build, but more important than all this he later gave the townsfolk their first charter, which bears the date May 2nd, 1194. During Richard's enforced detention in Austria, John de Gisors, Lord of the Burg of Portsmouth, formed a conspiracy against Richard. For this he was punished by the forfeiture of all his lands. The charter granted to the forfeited town conferred very important privileges on the burgesses, for which they had to pay into the king's exchequer £18 a year. The burgesses were now in a position to regulate trade with Normandy and other places and to extract fees from travellers who visited them. The proceeds thus obtained could be used for the benefit of the town and not for lining the pockets

of the manor lord. The charter was given by the hand of Bishop William Longchamps, and contrary to all precedent he used a personal seal which had as its device a crescent and a star with eight wavy rays. These since the fourteenth century have always appeared on the borough arms.

The number of people living in Portsmouth up to Richard's time could not have been large. There was only one church on Portsea Island. That stood between the three manors of Copnor, Fratton, and Buckland (Portsea), on the site of the present church of St. Mary, Kingston. If it were in existence

it would be the oldest building in Portsmouth. It was under the control of the Priory of Southwick. There is mention of it in 1166, and that it was dedicated to St. Mary. The remains of it were finally cleared away in 1843. The pathway from this church to Old Portsmouth can still be traced on the borough map. The oldest building in Portsmouth is the Church of St. Thomas. In 1180 (fourteen years before the granting of the charter) "John de Gisors gave an acre of his town of Portsmouth to the Black Canons of Southwick—serving God on the far side of Portsmouth Hill—to build thereon a Chapel to St. Thomas the Martyr." It is not recorded that he provided the cost of the building, but he gave the convent certain properties in the neighbourhood for the perpetual upkeep of the fabric. The Chapel of St. Thomas was not originally a parish church for Portsmouth. St. Mary's was the mother church of the island, and with its daughter chapel, St. Thomas's, was the property of the Prior and Canons of Southwick. According to Messrs. Lilley and Everett:

"The work of St. Thomas's about the year 1230 was carried on by two of these Canons a senior and a junior assisted by a Chaplain

and two Clerks in minor orders. They appear to have lived, all of them, in a Clergy-house at the corner of St. Thomas Street and Lombard Street on the East side of the latter diagonally opposite the Churchyard. The house had a garden by the side famous in later times for the succulence of its Warden pears. There was another garden on the North side, surrounded by a wall—a quasi-cloister—where the Canons could study their holy books and watch the grapes ripening."

The next oldest building on the island is the Domus Dei, of which more anon.

## England and Wales.

### WILLESDEN WAR MEMORIAL HOSPITAL.

The first pavilion of the new war memorial extension of the Willesden Hospital was opened on December 15th, 1922, by Viscount Burnham. The Willesden Hospital was founded as a cottage hospital of eight beds in 1892, and was enlarged to twenty-five beds in 1899. The war led to an addition of forty beds, and the latest extension will provide a total of 120 beds. Another pavilion is to be opened next year, chiefly to increase the accommodation for the nursing and domestic staffs. The pavilion which has just been opened consists mainly of a number of private wards for paying patients; each holds one or two patients, who will pay from three to six guineas a week. Lord Burnham, in unveiling a tablet which commemorates the raising of £1,000 by the school children of Willesden for the new hospital, said that, to his mind, no part of the national equipment, about which they had good reason to be proud, was so remarkable and efficient as the voluntary

hospital system. Lord Riddell and the Bishop of Willesden also spoke, paying eloquent tribute to the excellent work done by the Willesden Hospital.

### MANCHESTER PATHOLOGICAL SOCIETY.

At a meeting of the Manchester Pathological Society held on December 13th, 1922, with Professor Shaw Dunn, the President, in the chair, Mr. Sampson Handley read a paper on the "Pathology of the lymphatic system." Mr. Handley limited the scope of his discourse to a consideration of the nature of lupus, endeavouring to show that it is largely a lymphatic disease, that it spreads in the deep fascial lymphatics, and that the isolated nodules beyond the edge of the skin ulcer come about by extension along these vessels. Many sections were shown bearing out this hypothesis, and illustrating the absence of a network of lymphatics in the skin itself, so that lymphatic extension in the skin must needs take a circuitous course. Complete eradication of a focus of lupus can only be said to have been effected when the fascial lymphatics have been dealt with. In the discussion which

followed Professor Jamieson of Leeds did not appear to be quite satisfied that our knowledge of lymphatic supply and of the physiology of lymphatic flow was sufficiently definite to warrant absolute conclusion in pathological matters.

## Scotland.

### GLASGOW ROYAL INFIRMARY.

THE Lord Provost of Glasgow, Sir Thomas Paxton, presided at the time-honoured meeting between the managers and the nursing staff of Glasgow Royal Infirmary on New Year's Day. In his speech to the nurses the Lord Provost took occasion to refer to the early work of Lister in the old Royal Infirmary, and expressed the hope that it might yet be found possible to preserve the old ward, in which Lister worked, on its present site as a memorial of the great service Lister rendered to humanity. The Chairman of Managers, Mr. James Macfarlane, referred to the satisfactory and encouraging position of the infirmary, despite the time of severe industrial depression. With a continuance of public support he hoped that the completion of the reconstruction scheme could soon be proceeded with. The gate-house block would come first, and thereafter it was hoped to erect a new ophthalmic department on a site adjacent to the infirmary. What the managers required was more ground, and then the retention of the Lister ward would become possible, though not on its present site, which was needed for infirmary purposes. The university authorities had accepted the offer of the ward for re-erection in their grounds, but owing to lack of space they had to relinquish the idea. There was still less space available in the infirmary grounds as the managers desired to utilize all their space for the healing of patients, and the comfort of the suffering and those engaged in that noble work. He made bold to say that if Lord Lister were alive he would be the first to commend the position of the managers. He hoped still to see the Lister ward removed and re-erected on some suitable site in Glasgow. The treasurer gave some account of the financial position for the year just completed. General annual subscriptions for the year were £126 short of 1921, and employees' subscriptions, though reaching £28,902, showed a diminution of about £2,000. Considering trade conditions, this total showed that the working classes continued to take a very practical interest in the infirmary. Ordinary income was exceeded by expenditure by £24,325, but legacies and special donations amounted to £39,185, which after squaring the deficit in ordinary revenue left £14,860 for capital account.

### EDINBURGH ROYAL INFIRMARY.

The report of the managers of the Edinburgh Royal Infirmary for the year ending September 30th, 1922, shows that the total number of patients treated during the year was 14,156, as compared with 13,635 in the previous year—an increase of 721. The largest number of in-patients on any one day was 914, as against 900 in the previous year, and the average time each patient was under treatment was 22.1 days, as against 22.2 days. The percentage of deaths to cases treated was 6.5, but if the 238 deaths occurring within forty-eight hours of admission were deducted the percentage was reduced to 4.9, or 0.5 less than in the preceding year. In addition to the 14,156 in-patients there were 42,342 out-patients. The total ordinary income was £99,171, as compared with £118,191 in 1921. Voluntary contributions amounted to £65,712, a decrease of £17,332, as compared with the preceding year, but this was mainly due to the sum of £16,097 received in 1921 from the National Relief Fund. The combined contributions from individuals, business firms, public works and establishments, the League of Subscribers, and churches, showed an increase. The League of Subscribers had raised a total sum of £18,333, and its membership is now 85,000. The ordinary expenditure for the year was £119,759—a decrease of £13,569 as compared with the year 1921. The chief economies were effected in the house steward's department, owing to a fall in the cost of food; in the medical department, chiefly due to favourable purchases made at the Government Disposal Board's sales; and in the works department, owing to a decrease in the cost of fuel and the tonnage consumed. The extraordinary income (legacies and donations of £100 and over) amounted to £80,177, while the extraordinary expenditure was £5,740, chiefly expended upon the venereal diseases department and

the medical electrical department. The income of the improvements and extension fund amounted to £3,249. The cost per occupied bed was £136 14s. 3d., which was a decrease of £16 14s. 4d. on that of the previous year.

### SIR NORMAN WALKER.

The Scottish Board of Health has sent the following minute of congratulation to Dr. Norman Walker:

"The Board resolved to record their deep satisfaction that the honour of knighthood should have been conferred on Dr. Norman Walker, to whom the Board have been frequently indebted for valuable assistance and advice—more especially in his capacity first as vice-chairman and latterly as chairman of the Medical and Allied Services Consultative Council. The Board offer Dr. Walker their hearty congratulations and good wishes."

### TREATMENT OF TUBERCULOSIS IN PERTHSHIRE.

At a meeting of the Perthshire County Council in December it was stated that the Scottish Board of Health had approved of the plans for a joint Perth county and city sanatorium at Muris House, Errol, with seventy-five beds. The estimated cost of the scheme was £61,000, towards which a Government grant of £13,500 would be made, the remainder being provided by the county and the town council of Perth in a proportion of three-fourths to one-fourth. Discussion centred round the financial aspect of the question. Lord Forteviot said that in 1903 an estimate had been received from a Glasgow firm to erect a sanatorium of eighty beds for £9,200, while in 1919 an estimate for the same number of beds was £22,200; the latest estimate for a similar building from the same firm amounted to £32,000. He did not, therefore, think they were justified in accepting an offer for less accommodation at £61,000. After further discussion it was unanimously agreed that the Board should be asked to reconsider the whole matter.

## Ireland.

### FREE STATE MINISTRY OF LOCAL GOVERNMENT AND POOR LAW MEDICAL OFFICERS.

THE Irish Medical Secretary of the British Medical Association recently addressed a letter to the Ministry of Local Government (Irish Free State) with regard to the salaries of Poor Law medical officers engaged in the administration of the Medical Charities Acts, and the pensions of certain medical officers of Union hospitals who are compulsorily retired as the result of the recent amalgamation schemes of workhouses. The Minister of Local Government has in reply stated "that the aim of the Ministry is to secure that the salaries of the officers should be fixed on a suitable homogeneous basis for the whole country. To secure this result the Ministry are prepared to consider favourably revised scales of salaries for medical officers in each county in which such scales are necessary to remove existing anomalies. Meantime the Minister does not see his way to sanction any scales in excess of the existing highest scale for dispensary medical officers." The Minister also stated, with regard to the representations made as to the grievances of certain medical officers who were pensioned under the amalgamation schemes, that the Ministry will be prepared to look into any individual cases in which specific grievances are alleged.

### TUBERCULOSIS SCHEME FOR COUNTY MONAGHAN.

A deputation consisting of local clergymen and Dr. J. T. Elliott, secretary of the Co. Monaghan Local Medical Committee, recently waited on the county council to urge that the tuberculosis scheme should be continued, and that steps should be taken to extend it on a wider basis than heretofore. The council agreed to adopt the suggestion and decided to appoint a whole-time tuberculosis officer for the county at a salary of £500, with £100 travelling expenses.

### DAIRY AND COWSHED INSPECTION.

Lurgan and Moira Rural District Councils have decided to oppose the Belfast Corporation's bill seeking powers to control the inspection of dairies and cowsheds in the rural districts, on the ground that such powers would be calculated to set up a system of dual control which would be highly unsatisfactory. On the other hand, the Belfast Corporation justifies the main purpose of its bill on the ground that it should have a voice in the sanitation of these rural districts, from which is derived a considerable proportion of the milk supply distributed to the citizens of Belfast.

## Correspondence.

### APITUITARISM AND THE ANENCEPHALIC SYNDROME.

SIR,—In a brief article under the above heading in your issue of January 6th, 1923, Dr. D. L. Barlow shows that the anterior glandular portion of the pituitary gland was present in each of four anencephalic foetuses examined by him. These facts dispose conclusively of Dr. F. J. Browne's evidence for the suggestion that anencephaly is associated with faulty growth of the pituitary gland.

I wish to add one further instance in support of Dr. Barlow's proof. In 1911 I examined a fresh anencephalic foetus, in which not only the brain but all the spinal cord was absent; the peripheral nervous system and ganglia were present, as described in the case dissected by Sherrington. My own interest was then in the condition of the adrenal glands, but naturally I looked at the same time for the pituitary. A fully formed, well vascularized mass of glandular tissue (*pars anterior*) was easily identified. The microscopic sections show the same appearance as that figured in Dr. Barlow's article.—I am, etc.,

University College Hospital, W.C.1,  
Jan. 6th.

T. R. ELLIOTT.

SIR,—In your issue of January 6th (p. 15), under the heading "Apituitarism and the anencephalic syndrome," Dr. Barlow states that in four anencephalic foetuses he has found evidence of the presence of the *pars anterior* of the pituitary gland, and deduces from that the fact that the anencephalic syndrome described by me is no proof of the functions of the pituitary or that the internal secretions of the mother play only a very minor part in the development of the foetus.

The main object of my paper was more to draw attention to the anencephalic syndrome than to the apituitarism to which I attributed well marked cases of it. Whether the condition present in the anencephalic foetus was one of *hypopituitarism* is a point of minor importance. Indeed, there is no doubt that in many cases, probably in most, some pituitary tissue is present, for it is almost certain that its deficiency is due, not to developmental causes, but to destruction of the gland at an early period of its growth, in consequence of its exposed position on the floor of the basis cranii. I believe the amount of destruction varies in different cases, and that in certain instances it may so far progress that no trace of pituitary tissue may be found even on microscopic examination of the entire mass of tissue overlying the sella turcica. On the other hand, a considerable amount of vascular connective tissue intermixed with nerve cells may so protect the gland that little or no destruction of it may occur. This being so, the anencephalic syndrome to which I drew attention will vary in its degree and may in certain cases be almost entirely absent. The writer of the leading article in the BRITISH MEDICAL JOURNAL to which Dr. Barlow refers says: "Some anencephalics do not show the syndrome completely. Some are of what may be called the pretty type. . . . Now, it would be most interesting to know whether in these less ugly specimens there are traces of the pituitary gland." From the description of the four specimens examined by Dr. Barlow it seems probable that all belonged to this so-called "pretty" type, and that in none was the anencephalic syndrome as described by me at all well marked—that is, protruding eyeballs due to the smallness of the orbital cavity and the large pad of fat behind the eyeball, increase of the subcutaneous fat, protrusion of the tongue due to smallness of the mouth cavity, *hyperplasia* (not *hypoplasia* as stated in Dr. Barlow's paper) of the thymus, and *hypoplasia* of the genitals. For example, in specimen No. 4 the "adipose tissue was of about average amount." In a good example of the syndrome one of the most striking features is the great depth of subcutaneous fat which in one of my specimens measured 1 inch in depth over the manubrium sterni. To what is this to be attributed if not to pituitary deficiency?

That thymus hyperplasia exists in the anencephalic foetus when the syndrome is well marked there is no possibility of doubt. I have worked out the mean weight ratios of the thymus in over 200 infants, and in those of 8 to 9 months' development (most anencephalic foetuses are premature) found it to be 324, the heaviest ratio being 160 and the lightest 751. In four anencephalic foetuses, on the

other hand, in each case, adding one-eighth to the body weight to compensate for the absence of the brain, the thymus ratio was 94, 167, 95, and 331. In two of these cases the abnormal appearance of the thymus was most striking; quoting from my notes:

"It is a remarkably large and octopus-looking structure, consisting, in addition to the main mass, of several smaller lobes: weight 17 grams, weight ratio 94. It extends on the right side as far as the outer end of the clavicle, displacing the lung and filling the greater part of the lung space; on the left this is even more marked, the gland filling the entire upper part of the pleural cavity. The lungs on each side are rudimentary, and occupy only the lower part of the chest, having been evidently pushed down by the gland, which seems to have also interfered with their growth. Below the mid-line the thymus reaches to the diaphragm. A fairly large accessory thymus is present, and seems to be attached to the lower border of the left lateral lobe of the thyroid."

I have only once, apart from anencephaly, met with a weight ratio approaching those above quoted. In that case the infant was at term, and the ratio was 116. Apart from that one case the heaviest weight ratio I have ever met with at any age was 153. How is this hyperplasia to be explained? It surely cannot be a mere coincidence that by far the heaviest thymus glands I have ever met with were found in two out of the first five anencephalic foetuses which I examined.

The most marked example of the anencephalic syndrome that I have met with, and the one in which the above described thymus was found, was in my first specimen of anencephaly, upon which my conclusions were mainly based. In this naked-eye and microscopic examination failed to reveal evidence of pituitary tissue. In later specimens the syndrome has been less well marked, and in them I have more than once found evidence of the presence of varying amounts of pituitary tissue, but in all cases less than normal. That I did not claim its entire absence in every case is proved by the fact that I stated in my paper (p. 1), "in the monster under discussion we have a foetus which by virtue of its placental attachment to the mother is able to develop in utero to term frequently at least without any trace of a pituitary gland." In consequence of later findings I have been accustomed in conversation and in writing to refer to the condition in the anencephalic as one of *hypopituitarism* or *apituitarism*.

I have never seriously claimed that the hypoplasia of the adrenals, which I believe invariably present in anencephaly, is a part of the anencephalic syndrome.

So striking has this variability of the intensity of the syndrome above referred to been that in my notes of cases I have been accustomed to describe it as "well marked," "poorly marked," etc.

The sum of the matter seems to be this, that the title of my original article was somewhat unfortunate. Had it been "The anencephalic syndrome in its relation to apituitarism or hypopituitarism" my position would then have been unassailable.—I am, etc.,

Edinburgh, Jan. 8th.

F. J. BROWNE.

### THE TREATMENT OF GYNAECOLOGICAL CONDITIONS BY X RAYS AND RADIUM.

SIR,—In Dr. Knox's paper on the treatment of gynaecological conditions by x rays and radium, in your issue of October 14th, 1922 (p. 678), appears the following: "In other words, can the x-ray method compare with the surgical so far as complete removal is concerned? The answer must be in the negative."

Yet what surgeon would believe that he is able to eradicate the multitude of lymphatics and glands of the pelvis in their immediate relations to the numerous and important blood vessels, especially the aorta and the iliacs, although such might readily be accessible to x rays of sufficient penetration and intensity even though containing microscopic quantities of malignant cells?

Further on appears: "Another factor of some importance is the response of the tissues to the radiation. Some may only require a large quantity of relatively long wave-lengths, while in others the shortest wave-length of the gamma rays of radium may be more suitable." If by this Dr. Knox implies that it is the actual wave-length in any specific case which is characteristic for any desired response, it would be interesting to know on what evidence he bases this opinion. The numerous experiments carried out by Kroenig and Friedrich indicate clearly that a therapeutic effect can be obtained with a definite quantity of radiation quite irrespective of the quality.—I am, etc.,

Victoria, Australia, Dec. 1st, 1922.

H. FLECKER, F.R.C.S.

DISAPPEARANCE OF RODENT ULCER AFTER  
ERYSIPELAS.

SIR,—I do not know whether the case I am about to relate exhibited marked leucocytosis, as the blood was not examined; but without that provision it may be accepted as supporting the contention of Dr. John T. MacLachlan (December 30th, 1922, p. 1280).

Within the last three years a paucal patient under treatment for slight complaints from time to time was advised by me to have a small rodent ulcer at the left inner canthus removed by surgical operation. He refused this, and I observed the gradual enlargement until it became the size of a sixpenny piece. I was finally called in to treat him for an attack of erysipelas in the face. I noticed that the poison had entered by way of the ulcer and spread down over the left cheek. The attack was not severe, and I left him in a fortnight's time with a box of zinc ointment to apply to the ulcer, which remained red and angry. A month or two later I was informed by friends that my ointment had "cured the cancer." This seemed too flattering to be true, so I called on him to make sure. I then found that the ulcer had entirely disappeared, and only a supple white scar remained.—I am, etc.,

London, N.W., Jan. 5th.

HOPE GRANT, F.R.C.S.Ed.

NON-MALIGNANT AFFECTIONS OF THE COLON  
(INTESTINAL STASIS).

SIR,—I feel that Mr. Paramore, when dealing with the "physics" of the abdomen in your issue of December 9th, 1922 (p. 1145), has rather overlooked the fact that it would require an enormous and continuous lateral pressure to support a weight in such a well lubricated cavity as the abdomen. The moving intestinal contents are such a weight, and I have a strong suspicion that very many cases of stasis are connected with displacement of the gut, either by gravity or by the loaded portion being squeezed out of place by the abdominal muscles, much like a cherry stone from between the fingers. This may result, secondarily, in a local inflammation which increases the effects, or if a slight inflammation first led to the collection this may be increased. Here manipulation may help.

I would agree in deprecating too much surgical interference, for I feel that the future treatment of such conditions and all "indigestions" depends on the study of the specific action of drugs on the different parts of the gut, inch by inch almost, together with the almost specific results of local stases, whether these be "burned tongue," a localized cutaneous eruption, or (possibly) an attack of gout.—I am, etc.,

London, N.W., Dec. 22nd, 1922.

L. WALLACE, M.B.Oxon.

## THE DEVELOPMENT OF LOA LOA IN CHRYSOPS.

SIR,—In the BRITISH MEDICAL JOURNAL of October 21st, 1922, I notice in the article by Drs. A. and S. L. M. Connal on "The development of *Loa loa* in Chrysops," on page 730, that it is stated that the geographical distribution of *Loa loa* and of Calabar swelling is limited to West Africa. In this connexion the following note may be of interest. When I was in Yambio in the Bahr el Ghazal province of the Southern Sudan in 1914 I found Chrysops in fair number. I found no cases of Calabar swellings among the natives, but two years later I met in Cairo one of the men with whom I had lived in Yambio. He told me that since he left on furlough in 1915 he had suffered from peculiar swellings and irritation in his hands and arms. He spent his furlough in Australia, and said that he had puzzled the doctors whom he saw about this condition; one at last told him that his sickness was due to Calabar swellings, and that he was the first case of this complaint to be seen in Australia. He had never been in West Africa, and travelled to Australia via Egypt.—I am, etc.,

## TRAUMA AND APPENDICITIS.

SIR,—Dr. Charles J. G. Taylor's report of two cases under the heading of "Trauma and appendicitis" (January 6th, p. 17) leads me to mention a case that I have at present under my care in the Leicester Royal Infirmary.

A boy aged 12 years was playing football in the afternoon of Saturday, December 23rd, 1922, when he was kicked in the right lower abdomen by another boy. He was so badly hurt that he had to be taken home at once and put to bed. His

condition got worse and he was brought into the infirmary on the afternoon of December 26th. I saw him shortly after admission and it was at once obvious that he had some grave intra-abdominal lesion. Immediate lower median laparotomy was performed and extensive suppurative peritonitis throughout the lower abdomen disclosed. This was found to be due to a gangrenous appendix, which was removed and the pelvis drained. He is making a good recovery.

The boy tells me he was perfectly well before he was kicked. If the injury and the appendicitis are merely a coincidence it is a most extraordinary one.—I am, etc.,

Leicester, Jan. 8th.

F. BOLTON CARTER.

## HOSPITAL POLICY.

SIR,—The chief point now seems to be to find a formula which will unite those who still sincerely desire to maintain the voluntary principle and at the same time recognize that other factors have come into play. Therefore I suggest that if there must be a Medical Staff Fund it should consist—

1. Of voluntary contributions.

2. Of contributions from contracts made with the State, local authorities, employers of labour, and other bodies, where such contracts exceed the cost of maintenance in order to contribute to the medical fund.

This proposal is simple, honest, logical, and covers the hard cases in industrial districts. "Hard cases make bad law" is a well recognized axiom, but if we can meet them without infringing the voluntary system, which is infinitely more important than the hard cases, we must do so. If a Board of Management is convinced that a hard case exists in its hospital—and any Board should be open to conviction—it would be encouraged to contribute to the Medical Staff Fund.

This proposal does not prejudice the future because it frankly recognizes the present realities of the situation, and future policy would depend on how the profession was exploited by the laity. It need not be exploited at all if good will prevails. To force the present official policy is really to take advantage of the present difficult position of voluntary hospitals, and this is surely repugnant to us. We ought to be fighting to maintain the voluntary hospital, and not to undermine its position. The official policy was started in a somewhat obscure way when some people thought the voluntary system was doomed. The position has now changed by hospitals waking up and finding new sources of income. Surely we should welcome this instead of trying to turn it to our advantage.—I am, etc.,

Leitchworth, Jan. 6th.

NORMAN MACFADYEN.

## Universities and Colleges.

## UNIVERSITY OF LONDON.

THE University medal at the M.B., B.S. examination for internal and external students, October, 1922, has been awarded to Samson Wright, of the Middlesex Hospital.

Mr. F. J. Cleminson has been recognized as a teacher of otolaryngo-rhinology at the Middlesex Hospital Medical School. Sir William Willcox has been elected chairman of the Physiological Laboratory Committee. Sir Cooper Perry has been appointed a governor of Royal Holloway College, and Dr. P. H. Mitchiner a governor of Reigate Grammar School.

A course of lectures on mental deficiency for medical officers to local authorities and medical men engaged on work for defectives will be held, at the request of the Council of the Central Association for Mental Welfare, at the central buildings of the University from May 28th to June 2nd, 1923. Amongst the lectures arranged by the Faculty of Natural Science at King's College is one by Dr. J. S. Haldane, F.R.S., on the fundamental conceptions of biology, on February 7th.

Three lectures on psychology and psychotherapy will be given in the Department of Psychology at King's College by Dr. William Brown, on Mondays at 5.30 p.m., beginning on February 19th.

## LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD.

TWENTY-THREE scholarships and exhibitions of an aggregate total value of about £3,035, open to men and women, and tenable in the Faculties of Arts, Science, Medical Sciences, and Engineering of University College, King's College, and Bedford College, will be offered on May 1st. Fifteen medical entrance scholarships and exhibitions of an aggregate total value of about £1,530, tenable in the Faculty of Medical Sciences of University College and King's College, and in the medical schools of Westminster Hospital, King's College Hospital, University College Hospital, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital, will be offered for competition on Tuesday, June 26th. Full particulars and entry forms may be obtained from the Secretary of the Board, S. C. Ranner, M.A., The Medical School, King's College Hospital, Denmark Hill, London, S.E.5.

## REPORTS ON DRUGS.

## CHLOROFORM AND ETHER.

We have received from Messrs. J. F. Macfarlan and Co., Edinburgh and London (9, Moor Lane, E.C.2), samples of chloroform and ether prepared by them. We find that both samples comply with the B.P. tests for purity, and inhalation tests do not disclose any difference between them and other standard samples of these anaesthetics.

Messrs. Macfarlan claim that their products can be obtained at about one-third the cost of those made from ethylic alcohol. They point out that since chloroform and ether are definite chemical substances, therefore their purity does not depend upon the raw materials used in their manufacture, but upon the skill and care with which they are prepared.

There is certainly no scientific evidence against this claim. As regards chloroform, the Anaesthetics Committee of the British Medical Association, which made a prolonged investigation of undesirable effects due to anaesthetics, stated in its report (1900) that "comparing 'pure,' 'methylated,' and other chloroforms, no evidence is afforded of one kind being safer than another." Sir William Ramsay in the same report stated that all standard samples of chloroform left the manufacturer's hands in a highly pure condition, and that the presence of undesirable side-products such as phosgene ( $\text{COCl}_2$ ) was due to exposure to light and air, owing to the drug being stored in an improper manner.

The problem of ether has been complicated by the conclusions of Cotton and of Wallis, who claimed that pure ether had a low anaesthetic power, and that its action was increased by the presence of carbon dioxide and ethylene and other substances. In this connexion it is of interest to note that Stehle and Bourne<sup>1</sup> prepared highly pure ether and found that it had the same anaesthetic power as ordinary ether, or as the combination recommended by Cotton.

There is therefore no certain evidence that the action of anaesthetic ether depends on the presence of any other substance than ethylic ether. The chief requirement for anaesthetic ether appears to be that it should be a pure product and free from traces of such irritant substances as mercaptans.

## ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee 31 cases were considered and £417 granted to 29 applicants. The following is a summary of some of the cases relieved:

Son, aged 18, of M.D.Lond. who is now insane. The applicant is now at a training college and a bus training. The friend the £100 required. The

R.C.P.Edin. who died in 1920. asked the Fund to help her to purchase outfit. The sum of £72s. 2d. was paid by the Royal Medical Benevolent Fund Guild, and the Fund voted the sum of £4 towards this amount.

Widow, aged 40, of M.B.Lond. (1904), who died in 1918. Applicant was left to provide for her two children, aged 9 and 7, and asked for help towards education, but as her income is in excess of the condition of help from the Fund they voted the sum of £1 to qualify her for assistance from the Royal Medical Benevolent Fund Guild in helping to get the son into Epsom when old enough.

Widow, aged 45, of M.B., C.M. (1893), who died in January, 1912, leaving only £120 for applicant and three sons. This case received grants from the War Emergency Fund, and at present this Fund is paying the sum of £45 for one year's school fees for the youngest son. Another fund is helping with the maintenance grant, and the current expenses of the twelve months have reduced the applicant's balance to £30. The older son is a clerk who earns £100 per annum, out of which he gives his mother £43 towards his keep. The youngest son is a clerk who earns £78 per annum.

his applicant was owing to ill health. He was granted by the Fund in March, 1922, £26 in . . . was chosen as the most deserving to receive . . . of £2 which has been given to the Fund for a suitable unmarried grantee.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed in these days of exorbitant prices for clothing and household necessities with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 45, Bolsover Street, W.1.

## Obituary.

D. G. THOMSON, C.B.E., M.D.,

Late Medical Superintendent, Norfolk County Medical Hospital;  
Past President, Medico-Psychological Association.

We much regret to record the death of Dr. D. G. Thomson, for many years medical superintendent of the Norfolk County Mental Hospital, and from 1915 to 1919 commanding officer of the Norfolk War Hospital, with the rank of lieutenant-colonel R.A.M.C. He had recovered sufficiently from a recent severe illness to be able to spend Christmas with his son-in-law at Lingwood, near Norwich; but soon after he had a relapse and died on January 4th.

David George Thomson was born at Edinburgh in 1855, the son of Thomas Thomson of Princes Street. His younger brother is Professor Alexis Thomson, the distinguished Edinburgh surgeon. After studying in the University of Edinburgh and at Dunkirk and Dresden, he graduated M.B., C.M.Edin. in 1878, proceeding M.D., with honours, in 1881. Having served as house-surgeon at the Edinburgh Royal Infirmary, he began to apply himself to the study of mental disorder, and held in succession the post of assistant medical officer at the Derby County Mental Hospital and at Camberwell House, London. He was next appointed senior assistant medical officer to the London County Asylum at Cane Hill.

At the close of 1886 he was appointed medical superintendent of the Norfolk County Mental Hospital at Thorpe, Norwich, and held that office with great distinction for the long period of thirty-five years. During that time the institution grew much in size, and many and great improvements were effected. In July, 1914, the centenary of the opening of the hospital was commemorated by the holding of the annual meeting of the Medico-Psychological Association of Great Britain and Ireland at the hospital, under the presidency of Dr. Thomson. His presidential address gave an account of the development of psychological medicine in the preceding hundred years, together with a short history of the Norfolk Mental Hospital during that period, the oldest institution of its kind in this country. In this he discussed the origin and evolution of the laws relating to the insane, the growth of humanity in the treatment of the mentally afflicted, and the progress of the science of psychiatry. Twelve months later, towards the end of the first year of the war, the Norfolk Mental Hospital was taken over by the War Office for conversion into a military hospital, with Dr. Thomson as commanding officer. How the difficult task of reorganization was faced and accomplished was described by him in a paper in the *Journal of Mental Science* in 1916 and in an appendix to his Annual Report for 1920. Transport arrangements by road and rail had to be made for evacuation of the mental patients and their accompanying staff and documents. Within twelve days 950 persons were safely transferred to Ipswich, Melton, Colchester, Brentwood, Aylesbury, St. Albans, Arlesey, Godmays, and Cambridge. Some of the patients had been at the asylum for over fifty years and could remember no other home; many had never been in a railway train. Then came the necessary structural changes involved in the conversion of a large asylum into a military hospital of 1,000 beds at a cost of some £16,000. Eventually the total available accommodation of the Norfolk War Hospital grew to 2,423 beds, remaining at this figure from the spring of 1918 until its demobilization in April, 1919. During the four years and a half 45,000 sick and wounded soldiers passed through the wards.

In the autumn of 1915 Colonel Thomson took over the military supervision of all the auxiliary hospitals in Norfolk—some 60 in number—and these were henceforward affiliated to the Norfolk War Hospital for purposes of administration, inspection, and supply. This heavy task, like all other he undertook, was carried through with conspicuous success. For his war services Thomson was awarded the C.B.E., and retained his rank of lieutenant-colonel R.A.M.C. In December, 1919, the permanent heads of departments of the war hospital and the members of the medical staff made him presentations as a mark of their esteem and in remembrance of the privilege they all had of working under him during the war. Early last year, on retiring from the post of medical superintendent of the institution (once again the Norfolk County Mental Hospital), he was the recipient of a farther presentation, and was appointed medical adviser to the Mental Deficiency Acts Committee of the Norfolk County Council. In retirement at his home in Norwich he continued also to

<sup>1</sup> R. L. Stehle and W. Bourne: *Journ. of Amer. Med. Assoc.*, 73, 375, 1922.

act as Honorary Consulting Physician to the National Association for the Care of the Feeble-minded.

He remained in office as President of the Medico-Psychological Association throughout the period of the war. For many years he had lent his influence to the cause of reform, urging the need for properly equipped clinics for the treatment of early and incipient forms of mental disorder, and for the training of young medical practitioners in psychiatry. In 1919 his successor in the presidency, Dr. Hubert Bond, reviewed the progress that had been made towards realizing the measures powerfully advocated in 1908 by Thomson for providing adequate instruction in psychiatry. Besides his advocacy of mental clinics and schools of psychiatry, Thomson wrote and spoke on the need for removing the disabilities of the asylum medical service, and thus encouraging young graduates to look on psychiatry as a career in medicine.

Thomson was a loyal and devoted member of the British Medical Association and served it well in many capacities. He was Honorary Secretary of the East Norfolk Division from its formation in 1903 until 1920 and represented it on the Representative Body of the Association. He was a member of the Norfolk Branch Council, and was President of the old East Anglian Branch in 1909. In 1913 he received from the medical practitioners of Norfolk a presentation of plate in recognition of his great services to the Division and also of his work as honorary secretary of the Norfolk Insurance Committee. At the Annual Meeting of the Association held in London in 1910 he was Vice-President of the Section of Psychological Medicine and Neurology. He was for some years a valued member of the Medico-Political Committee, of the Medico-Legal Subcommittee, and of the Asylum Assistant Medical Officers' Subcommittee; and during the war, notwithstanding his many other duties, he found time to serve as secretary of the Local Medical War Committee for East Norfolk. From 1918 to 1919 he was a member of the Central Council of the Association.

The funeral took place at Lingwood on January 8th. Sir Hamilton Ballance represented the Council of the British Medical Association; Mr. Blaxland and Dr. Cleveland the Norfolk Branch; and Dr. Ian Dickson the Norwich Division of the Association. Representatives of the Norfolk Mental Hospital included Dr. O. G. Connell, medical superintendent, and Dr. A. W. B. Livesay, senior medical officer. The Board of Control was represented by Dr. C. Hubert Bond, who, together with Dr. Rice and Dr. Livesay, also represented the Medico-Psychological Association. The Norwich Medico-Chirurgical Society was represented by Dr. Crook, Mr. Maxted, and Dr. Starling.

The MEDICAL SECRETARY writes: I am glad to have the opportunity of paying my respects to the memory of one of the best British Medical Association workers I have known. He was not a man whose intimacy was easily reached, but those who knew him well realized his great ability, his soundness of judgement, his acute sense of humour, and, above all, his intense devotion to the Association. There was nothing the Association could ask of him that he was not prepared to do with all his might, though always keeping well out of the limelight. He was a signal refutation of the theory held by some that to do good work for general practitioners a man must be in general practice himself, because though Thomson had never been in general practice he was completely trusted by his constituents, who knew that he would never let them down. And well he deserved their trust. He regarded himself as the shepherd of the East Norfolk Division, and it was his pride to say, as he often did, that the Association could always depend on his men. He will be greatly missed by his friends in the Representative Body, of which he was a member and attended uninterruptedly from 1907 to 1922. I have lost one of my best friends in the Association, and wish to extend my sympathy not only to his family but to the East Norfolk practitioners, to whom for so many years he cheerfully gave of his very best.

HARRY RAINY, M.A., M.D., F.R.C.P.E.,  
Physician, Edinburgh Royal Infirmary.

DR. HARRY RAINY, one of Edinburgh's distinguished graduates, physicians, and teachers, died on January 4th at his residence in that city. For some months his health had been giving anxiety to his friends, and, although there had been improvement recently, the end was not unexpected. He was in his fifty-ninth year.

Dr. Rainy came of a family distinguished both in medicine and the church. His great-grandfather was George Rainy, minister of Criech in Sutherlandshire, and his grandfather was Professor Harry Rainy, a student of medicine both in Glasgow and Edinburgh, an M.D. of the former (1833), and the professor of forensic medicine and medical jurisprudence in its university (1841-62). Professor Rainy's second son, George, was also M.D. of Glasgow and surgeon to the Eye Infirmary there; he was the father of the subject of this notice.

Whilst Professor Harry Rainy of Glasgow played a leading part in the great ecclesiastical movement which terminated in 1843 in the Disruption and in the formation of the Free Church of Scotland, his eldest son, Robert Rainy, D.D., uncle, therefore, of the subject of this memoir, was a leader of the Free Church, Principal of New College, and Moderator of the first Assembly of the United Free Church in 1900. With such an ancestry it is no wonder that Dr. Harry Rainy made a mark in medicine and took more than a passing interest in church affairs. He was an elder in the New North United Free Church, Edinburgh, and an ardent supporter of the movement for union between the two churches whose separation constituted the Disruption in 1843.

Harry Rainy was born in Glasgow in 1864. He received his education in Edinburgh at the Academy and the University. He graduated M.A. in 1885 and M.B. and C.M. in 1891; he was the most distinguished student of his year in medicine, gaining the Ettles Scholarship. He built up an important reputation as a physician. He was among the first to use the x rays extensively in diagnosis. With his friend, Dr. Robert Hutchison, he wrote an admirable students' textbook entitled *Clinical Methods*, which, published in 1897, has passed through a number of editions. In 1895 he had passed the examinations for the membership of the Royal College of Physicians of Edinburgh and in 1896 he was elected to the Fellowship. He was soon appointed an examiner in medicine in that college; he acted for many years as honorary secretary; served for five years on the Council, and was for a time vice-president. In 1899 he graduated M.D.; his thesis, which was deemed worthy of competing for a gold medal, was on the action of toxic substances on spinal stichochrome cells. In 1907, when he attended the bicentenary celebrations of the birth of Linnaeus in Sweden as one of the representatives of the Royal College of Physicians of Edinburgh, he was given the honorary doctorate of medicine by the University of Upsala. Meanwhile Dr. Rainy was rapidly making his influence felt in Edinburgh: he was lecturing on the principles and practice of medicine in the Extramural Medical School; he was acting as one of the physicians to the New Town Dispensary; and he was doing good work as honorary medical electrician to the Royal Hospital for Sick Children. In 1912 he was appointed lecturer on physical methods in the treatment of disease in the University of Edinburgh; he was one of the physicians to the Edinburgh Royal Infirmary and extern examiner in medicine in the University of Aberdeen; and was elected a Fellow of the Royal Society of Edinburgh. Comparatively recently he succeeded Dr. Crauford Dunlop as medical adviser to the Prison Commission for Scotland; and just a few weeks before his death he was appointed physician to the Longmore Hospital for Incurables in place of the late Sir James Affleck. In 1918 also he was nominated by the University Court as senior lecturer on clinical medicine in charge of wards in the Royal Infirmary. During all these years of constant work Dr. Rainy found time to contribute to the literature of his profession; in addition to *Clinical Methods* he wrote on the pathology of Friedreich's ataxia, on congenital facial diplegia due to nuclear lesions, on skiagraphic researches in teratology, on clinical methods of estimation of sugar in the blood, and on dyspnoea (in the second edition of the *Encyclopaedia Medica*).

Dr. Rainy's qualifications were conspicuous in several directions. He was a deft administrator; his counsel, founded on great experience and on sure knowledge, was highly valued in all the public bodies with which he was associated, as for instance in the Governing Board of the School of Medicine of the Royal Colleges, where he was one of the representatives of the Royal College of Physicians. As an investigator of scientific problems he was critical to a degree, never failing to submit his own work to the same trial as by fire to which he subjected that of others. He was a fair, if searching, examiner, free from fads. As a teacher he showed something of the equipment of his revered master, the late Professor Greenfield; in other words, he delighted to educate his pupils by

helping them to demonstrate to themselves (and incidentally to others) their amazing lack of precise knowledge; but underneath his searching methods there was never lacking a redeeming and saving humour, often coming in where and when least expected, and always carrying away with it every trace of chagrin or soreness. It is reported that once when he was teaching clinical medicine to women students he remarked that the class notices were not being attended to, and that, in future, he had given orders they should be hung up immediately under the mirror on the wall of the dressing room! His humour peeped out too in the word *pluvium*, which he chose for his abbreviated telegraphic address.

As has been already noted, Dr. Rainy shared with his relatives an interest in ecclesiastical matters which was deeper even than that of the average Scotsman. He acted as superintendent of sabbath schools in his own congregation, and he was nearly always returned as a Representative Elder to the General Assembly of the Church. He was beloved by his patients, and his opinion as a consultant was placed high. There was yet another sphere in which he shone. His friends found that his mind was stocked with the best passages from the best authors; he was at home in the classics of all ages and times, from Plato and Euripides (how he loved Gilbert Murray's translations!) to Dante and Bunyan. It was no longer ago than New Year's Day that he showed with pride to the writer of this obituary notice an early edition of the *Divina Commedia* which he had recently acquired. Here, too, his sense of humour came in, for he enjoyed nothing so much as a clever parody such as Kipling and Graves have given of the almost unknown fifth book of Horace's *Odes*. He had a fine taste in music, too, and could discourse with understanding of the Gregorian chant. Dr. Harry Rainy leaves a place in medical Edinburgh which will not soon be filled, a place which he had made all his own and had furnished with gifts of intellect and character of unusual brilliancy and depth.

The funeral took place on Monday, January 8th, from the New North Church to Rosebank Cemetery, and was attended by the Vice-President and the Fellows of the Royal College of Physicians, by representatives of the University and Royal Infirmary, and many others.

A. MAXWELL WILLIAMSON, M.D., B.Sc.,  
M.O.H. City of Edinburgh.

DR. ALFRED MAXWELL WILLIAMSON, after a serious illness of some three months' duration, died on January 5th, at the Palace Hotel, Castle Street, Edinburgh, which had been his home for the past sixteen years. Like Dr. Harry Rainy, whose death occurred only a day before, Dr. Williamson never married; he gave all his time and energy to the work of his office as medical officer of health to the city of Edinburgh, and he achieved results of the highest importance to the Scottish capital and to the country at large.

He was the son of a medical man in Leith (now a part of the "extended Edinburgh"), and was born there in 1859. At first his bent was towards the sea, and he was trained as an engineer in one of the shipbuilding firms in his native town. Then he turned to the profession of his father and studied medicine in the University of Edinburgh, and graduated M.B. and C.M. in 1888 when he was 29 years old. He took the B.Sc. in Public Health in 1890, and from that time till his death his life was more or less intimately bound up with the maintenance of the public welfare of the city which was ultimately to be amalgamated with Leith; it is a somewhat interesting fact that some of the strongest arguments which in the end brought about this amalgamation were those founded on the desirability of conjoining in one the health activities of the two neighbouring towns. In 1899 Williamson graduated M.D. in the University of Edinburgh; his thesis, which was deemed worthy of competing for a gold medal, had as its subject the infectivity of tuberculous meat and the methods of tuberculous meat inspection employed in public abattoirs, and embodied a criticism of the report of the Royal Commission on Tuberculosis.

In 1891 Dr. Williamson was appointed an assistant to Sir Henry Littlejohn, then the active and distinguished medical officer of health for Edinburgh. He occupied this post for six years, acting for a short period as temporary medical officer in Sir Henry's absence, and again for a three months' interval performing the duties of Dr. Wood (then seriously ill) as medical superintendent of the City Hospital. Dr. Williamson was especially appointed to deal with the outbreak of small-pox in 1894-95 and with the system of free

vaccination which was then offered to the citizens. In 1898 he was made chief sanitary inspector to the city, and had the responsibility of organizing a new department and of getting to know the health conditions of the town in a way which enabled him later to work so efficiently in the post of medical officer of health, which, on the retirement of Sir Henry Littlejohn, became vacant in 1908. Events more than justified the wisdom of the choice which gave this important post to Dr. Williamson. He did other things than those that fell to him in his civic appointment—for instance, he was examiner in medical jurisprudence and public health for the Colleges of Physicians and Surgeons and in public health for the University; he had also been President of the Society of Medical Officers of Health of Scotland—but the business of the medical officership of health was his life-work.

Dr. Maxwell Williamson's tenure of office coincided with the coming into force of a number of legislative enactments which had a profound influence upon public health activities everywhere and gave a special tinge and character to his work. He was quick to see their bearing upon local conditions, and had a scheme ready for acceptance as soon as the way opened for it. It was so with tuberculosis (under the National Insurance Act), and rapidly provision was made at the City Hospital, at the Victoria Hospital, and elsewhere for the treatment of this disease; it was so again with mother and child welfare (under the Births (Extension) Act, the Midwives Act, and the Maternity and Child Welfare Act), and immediately centres (preventive and curative) sprang up all over the city, and the Royal Maternity Hospital and various dispensaries were swept into the City of Edinburgh Welfare Scheme; when the report of a Royal Commission and the discovery of better means for diagnosing and treating the venereal diseases brought these matters into the public eye the medical officer of health was prepared with a scheme to utilize all this at once for the well-being not only of Edinburgh but of many of the surrounding districts too. Sir Henry Littlejohn had foreseen many of these developments and had as far as possible prepared for them, but it fell to Dr. Williamson to carry them out and to witness a fall in the total death rate, a fall in the infantile death rate, and a lessening in the danger and destructiveness of the venereal diseases. Dr. Williamson never forgot his early experiences in the domain of housing, and most of the contributions which he made to medical literature (in addition, of course, to his vivid annual reports, which caused dry facts to live) were devoted to the housing problem. Thus he was the author of *Housing Conditions in their Relation to the Spread of Tuberculosis*, and he contributed to the second edition of the *Encyclopaedia Medica* an admirable article on housing, founded upon the Edinburgh conditions. He had from time to time anxious hours and days when epidemics swept over or near to the city, but he was then seen at his best, rapid and resourceful; and when mistakes were made—as on an occasion not so long ago—he was quick to recognize them and frankly to own an error and as quickly to set about on a right tack.

Dr. Williamson's care of the health of Edinburgh was well known; but to the few who were his intimate friends he seemed almost as if he added a responsibility for the ethical conditions of the city. He was deeply religious, and was much concerned by the temperance question and the social problems of city life with which he was so often in contact. He carried on a club for men and boys in the Cowgate, he was a director of the Free Breakfast Mission, and he was a constant supporter of temperance and evangelistic campaigns. He was an elder in St. George's United Free Church. The funeral at South Leith Churchyard took place on Sunday, January 7th, and was largely attended.

JOHN D. LLOYD, L.R.C.P., M.R.C.S.,  
Formerly of Chirk

DR. JOHN DANIEL LLOYD, M.B.E., J.P., who died on November 23rd, 1922, aged 73 years, received his medical training at the old Bristol School of Medicine, where W. G. Grace was one of his fellow students; he also studied at St. Bartholomew's Hospital, and took the diplomas of L.R.C.P. (Edin.) in 1873 and M.R.C.S. (Eng.) in 1874. Soon afterwards he joined a practice at Chirk, Denbighshire, where he spent the remainder of his working life. He was a justice of the peace for Denbighshire and held many public medical appointments; he was M.O.H. for Chirk and surgeon to Brynkinalt Cottage Hospital. He had held the rank of surgeon lieutenant-colonel in the Shropshire Yeomanry, and received the Territorial Decoration; he was also a Knight of Grace of the Order of St. John of Jerusalem.

For forty years Dr. Lloyd carried on successfully a very extensive general and colliery practice, and was held in high esteem by all who knew him. He took a great interest in public affairs and in the welfare of his profession; he was an active member of the British Medical Association, and had been president of the Shropshire and Mid-Wales Branch. He was a sagacious practitioner and a hard worker, who rarely took a holiday away from his practice. He was fond of all kinds of sport, and in his early days a successful steeplechase rider. He was an excellent judge of a horse and before motor cars came into regular use did his work on horseback. Occasionally, too, he was able to put in a day with the hounds. He was also interested in the gentle art of self-defence. During the later years of his life in Chirk he set himself the task of raising funds for a hospital at Chirk. He chose the site, arranged the aspect, and considered every detail of its construction. He laid the foundation stone, and before leaving Chirk had the satisfaction of seeing this hospital of sixteen beds in full working order. He was a man of sunny nature, whose geniality was appreciated even on a slight acquaintance. He has left behind him many friends to mourn his loss. He was laid to rest in Lillesley Churchyard, near Gloucester, where his wife and eldest son are also buried. He is survived by a son and a daughter.

#### JOHN BERRY HAYCRAFT, M.D., D.Sc.,

Emeritus Professor of Physiology, University College, South Wales.

PROFESSOR JOHN BERRY HAYCRAFT, whose death was briefly mentioned in our issue of last week, had retired from the Chair of Physiology, University College, South Wales, in 1920, when he was appointed Emeritus Professor. He had since resided in Cambridge, where he continued his physiological researches. A paper by him on the photographic kymograph is ready for publication in the *Journal of Physiology*, and just before he was attacked by his last illness he had completed a further series of experiments on the pulse.

John Berry Haycraft, whose father had the same Christian names, was born in London in 1857, and received his medical education in Edinburgh, where he graduated M.B., M.Ch., and B.Sc. in 1878; ten years later he took the degrees of M.D. and D.Sc. After working for some time in Ludwig's laboratory in Leipzig he became demonstrator of physiology in the University of Edinburgh under Professor Rutherford. After holding that position for nearly three years he was, in 1881, appointed to the newly founded chair of physiology at Mason College, Birmingham. His teaching in Birmingham was successful in attracting students, and in 1887 he accepted an invitation to take the place of Professor Rutherford, who was unable, owing to ill health, himself to conduct the classes and give the systematic lectures. When Professor Rutherford returned in 1888 Haycraft continued to take the practical courses and organized an advanced class of practical physiology. He remained in the physiological department in Edinburgh until 1892, when as the post of assistant professor of physiology, which he had been led to expect he would receive, had not been established, he went to London and was appointed a research scholar of the British Medical Association. During his years in Birmingham and Edinburgh Haycraft had been actively engaged in research and had published papers on the coagulation of the blood, a subject in which he took a deep interest; on the estimation of uric acid, on the nature of the striation of muscle, and on other subjects. In 1893, when the medical school of University College, Cardiff, was established, he was appointed to the chair of physiology, and again had the task of organizing the department. In 1899 he was laid aside for a year by an attack of hemiplegia, but made a remarkable recovery. About 1908 he began to insist on the need for a new physiological department, and his hopes were realized in 1913, when the erection of new buildings, made possible by the generous gift of Sir William James Thomas, Bt., was undertaken. Haycraft was responsible for the planning and equipment of the physiological department, which he continued to direct until 1920, when, as has been said, he retired. In 1894 he was appointed to deliver the Milroy lecture of the Royal College of Physicians, and took for his subject, "Darwinism and race progress." He was the author of the articles on animal mechanics, taste and smell in Schafer's *Textbook of Physiology* (1900), and of numerous articles in the *Journal of Physiology* and other periodical publications.

Dr. Haycraft was thrice married: his first wife, a sister of Mr. de Vere Stapoole, was an artist and writer. He leaves

a widow and two sons, one of whom is Mr. J. B. Haycraft, M.C., F.R.C.S., assistant in the surgical unit of the Welsh National School of Medicine, and honorary surgeon to the Prince of Wales's Hospital, Cardiff.

By the death of Sir FRANCIS FARMER dentistry loses a vigorous and inspiring personality. To the medical profession he was best known for his work as consulting dental surgeon to the Queen's Hospital at Sidcup. His skill and ingenuity in prosthetic dentistry were invaluable both to the operating surgeon and to the dentist. The dental profession knew him long before this as dental surgeon to the London Hospital and one of those who helped in the founding of the London Hospital School of Dentistry. He took a deep and practical interest in the dental museum of the school, which contains many specimens of his giving. Free of the cares of practice Sir Francis Farmer was a most agreeable comrade, and those who were privileged to know him will agree that as a teller of stories he was beyond compare. His sudden death will be deplored by all who knew him and his work.

We regret to record the death, at Coventry, on December 21st, 1922, of Dr. T. W. FOWLER, at the age of 61. Thomas Webb Fowler received his medical education at Queen's College, Birmingham, and took the diplomas of M.R.C.S. Eng. in 1885 and L.R.C.P. Lond. in 1887; he graduated M.B., Ch.B. of Birmingham University in 1901 and M.D. in 1906, and became F.R.C.S. Edin. in 1902. After practising for a few years at Matlock and at Birmingham, he went to Coventry in 1885 and built up a large practice there. In 1889 he was elected a member of the city council, and at the time of his death he was by length of service its senior member. Throughout his long public career public health claimed his closest interest; he brought to a successful issue schemes for a small-pox hospital and for an extension of the city hospital; he always kept a watchful eye upon the city's water supply and on his initiative a monthly analysis of the supply was instituted; he was for seventeen years chairman of the Watch Committee. In 1897, at the early age of 36, he was elected mayor of Coventry, and was re-elected at the end of his year of office. On the completion of his term he was raised to the aldermanic bench, and he was also a justice of the peace for the city. Dr. Fowler represented Coventry on the board of governors of Birmingham University, and had been chairman of the Coventry Education Committee. He held the appointment of honorary physician to the Coventry and Warwickshire Hospital, and was a member and a former president of the Coventry Division of the British Medical Association. He will long be remembered in Coventry for his energetic work in the interests of the city, for his high professional reputation, and for his kindness of heart.

WE regret to record the death of Dr. BERNARD PICKERING, which took place at his residence in Bolton on December 18th, 1922, after an illness which had lasted for about three months. He was born at Lichfield in 1881, and received his medical education at Edinburgh University, where he graduated M.B., Ch.B. in 1904. As a student he was an active member of the University Rowing Club. For three years he was house-surgeon at Bolton Infirmary, and on resigning entered into partnership with the late Dr. Jefferies. In May, 1915, he joined the R.A.M.C. and saw service in France, where he was surgical specialist in the 20th Casualty Clearing Station. Dr. Pickering was honorary assistant surgeon to the Bolton Infirmary; he was a member of the Panel Committee and had been secretary of the Bolton Medical Society. He was a quiet, unassuming man, who hated ostentation. So conscientious was he in his work and so ready to respond to all demands on his time, whatever the hour, that there is little doubt his health was so undermined as to diminish his recuperative power during his illness. His cheerful courage, his patience, and his consideration for others were characteristic, and never once failed him during his last illness. The affection in which he was held was shown at his funeral, when over thirty of his colleagues and many patients were present.

Professor JOLYET of Bordeaux, a well-known physiologist and biologist, has recently died.

Professor OBERSTEINER, the well-known neurologist of Vienna, has died at the age of 75.

## The Services.

### TERRITORIAL DECORATION.

THE Territorial Decoration has been conferred upon the following officers.

*Territorial Army: Royal Army Medical Corps.*—Majors H. A. Ahrens (ret.), R. Y. Anderson, E. H. Brunt (deceased), W. F. Muoro, M.C., and H. B. Low, M.C. (ret.).

*Territorial Army Reserve: Royal Army Medical Corps.*—Major W. A. L. Holland.

## Medical News.

THE celebration at the Royal Society of Medicine of the hundredth anniversary of Pasteur's birth, to which we made reference last week, will be held on February 28th. The Bulletin of the Académie de Médecine for December 26th, 1922, contains a report of the speeches made in celebration of the one-hundredth anniversary of the birth of Pasteur, of which our Paris correspondent last week gave a spirited account. The number is illustrated by a photographic portrait of Pasteur which we have not seen before. It is a striking likeness, showing him in the prime of middle life.

LIGHT is thrown on the attitude of the rulers of public schools to science by the reception accorded at the Head Masters' Conference last week to the report of the Science Masters' Association, made at the request of the conference and of the Associated Preparatory Schools, on the teaching of elementary science and nature study in preparatory schools. The report contained proposals that two periods should be given weekly to science, or a least one period of three-quarters of an hour, and that candidates for scholarships at public schools should have the opportunity of answering questions in science in *viva voce* examination. Mr. Talbot (Haileybury) in supporting the recommendations said that boys who had not done some preliminary science at the preparatory schools were handicapped at the public schools; in the period of a boy's life which immediately preceded the public school age (13) his natural disposition was to be keen in his inquiries about things, and this was the moment to introduce him to science. Mr. Eccles (Gresham's), though in favour of the recommendations, said that the preparatory school masters were opposed to them on the ground that any time taken from Latin tended to handicap the boys in scoring for scholarships at public schools. The head master of Eton expressed the view that the burden to be placed on preparatory schools was greater than they could bear, and eventually the conference rejected the proposal that where possible two periods weekly should be given to science, but agreed that candidates for scholarships at public schools should be allowed an opportunity of answering questions in science at the *viva voce* examinations.

A NEW course of lectures at the Hospital for Sick Children, Great Ormond Street, W.C.1, commenced on Thursday last, when Dr. Thurstield spoke on the diagnosis of pulmonary tuberculosis in children of school age. The lectures, which are free to medical practitioners, will be continued on Thursdays, at 4 p.m., up till and including March 22nd. The subjects are announced each week on the last page of the SUPPLEMENT.

A NEW post-graduate course will commence at the National Hospital for the Paralyzed and Epileptic, Queen Square, Bloomsbury, W.C.1, on January 22nd, and continue to March 23rd. The course will consist of lectures on the pathology of the nervous system, by Dr. J. G. Greenfield, on Mondays; out-patient clinics and clinical lectures and demonstrations on Mondays, Tuesdays, Thursdays, and Fridays. Lectures on the anatomy and physiology of the nervous system will also be given if sufficient entries are received.

A COURSE of lectures on tuberculosis and venereal disease has been arranged by the Royal Institute of Public Health. The lectures will be given at the Institute (37, Russell Square, W.C.1) on Wednesdays, at 4 p.m., from January 17th to March 21st inclusive. The lecturers are Professor Lyle Cummins, Dr. Gordon Pugh, Dr. Lisle Punch, Dr. James Watt, Dr. Hope Gosse, Colonel L. W. Harrison, Dr. Townley Clarkson, Major A. T. Frost, Dr. J. H. Sequeira, and Dr. W. J. O'Donovan. Admission is free, without ticket.

AN international congress of hydrology and climatology will be held at Brussels in September, when the hydro-mineral treatment of diseases of nutrition and of heart diseases will be discussed.

THE post-graduate lecture at the Whitworth Street West Branch of St. Mary's Hospitals, Manchester, arranged for January 19th, has been postponed till March 9th.

THE health organization of the League of Nations recently brought to a successful conclusion an international course for medical officers, in which twenty-two officials from the health services of Austria, Belgium, Bulgaria, Italy, Poland, Russia, and other countries took part. The course was held in Belgium and Italy during two and a half months, under the auspices of the directors of the Belgium and Italian health services respectively, through the aid of a grant from the Rockefeller Foundation. On the completion of the course those who took part in it assembled at Geneva, where a discussion was held on the results. Dr. D. C. Kirkhope, M.O.H. Tottenham, attended the course as an observer, as the next course is to be held in England.

THE annual meeting of the French Society of Comparative Pathology was held in Paris on December 19th, 1922, when papers were read on the action of the lung on fats, by Professor Roger; on articular and febrile symptoms of alimentary origin, by Professor Bezançon; on cancer of plants, by Professor Fock; on gonococcal phlebitis and periphlebitic abscess, by Achard, Rouillard, and Bloch; on therapeutic applications of d'Herelle's phenomenon, by Philibert, Handuroy, and Cordey; on researches on the physiological and therapeutical properties of tissue diastases, by Professor Maignon; on normal radiological pictures in the dog, by Taskin; on clinical applications of giant syringes, by Rosenthal; on biological causes of depopulation, by Bérillon; and on early diagnosis of pulmonary tuberculosis by x rays, by Faugère.

THE Lord Chancellor, Viscount Cave, will open the new Haslemere and District Hospital at 2 p.m. on Saturday, January 20th. The hospital is equipped for 35 beds, and has been built at a cost of £32,000, the whole of which has been raised, so that the institution starts free from debt.

THE scheme adopted last July by the Voluntary Hospitals Commission to establish a small consultative committee of members of local committees has now been carried out. Among the members are Sir David Drummond, C.B.E., M.D., representing the Northumberland Local Voluntary Hospital Committee, Sir A. Garrod Thomas, M.D. (Monmouthshire), and Colonel R. J. S. Simpson, C.B., C.M.G., late A.M.S. (Kent).

A DISCUSSION on the treatment of human trypanosomiasis will be held at the meeting of the Royal Society of Tropical Medicine and Hygiene on Thursday evening next; the value of the drug called "Bayer 205" and of tryparsamide will be discussed. Full details are to be found in the Diary.

THE question of the return of disabled men to industrial life will be discussed at the meeting of the Governing Body of the International Labour Office of the League of Nations to be held in Geneva on January 30th.

At a sessional meeting of the Royal Sanitary Institute to be held at the Birmingham University on February 2nd and 3rd a discussion on town and country milk supplies and their improvement will be opened by Dr. John Robertson, M.O.H. Birmingham; the chair will be taken by Professor H. R. Kenwood.

At the meeting of the Royal Statistical Society to be held at the Royal Society of Arts, John Street, Adelphi, W.C.2, at 5.15 p.m. on Tuesday next, January 16th, Dr. R. Duddfield will open a discussion on the registration of disease.

A MEETING of the Medical Prayer Union will be held by invitation of Dr. and Mrs. J. Burnett Rae, at 98, Portland Place, W.1, on Thursday, January 25th, at 8 p.m., when the Right Rev. E. A. Knox, D.D., late Bishop of Manchester, will read a paper. An intimation of intention to be present will be welcomed by the Hon. Secretary, Dr. Tom Jays, Livingstone College, Leyton, E.10.

THE annual meeting of the Canadian Medical Association will be held at Montreal on June 12th, 13th, and 14th. The Canadian Medical Association Journal states that among those present at the annual meeting will be Sir Berkeley Moynihan, Sir Robert Jones, Sir William Taylor of Dublin, and Dr. W. J. Mayo of Rochester, U.S.A. Arrangements have been made for the meetings of other associated societies to take place at the same time.

THE next international congress of the history of medicine will be held at Geneva in 1925.

At the meeting of the Medico-Legal Society to be held at 11, Chandos Street, W.1, on Tuesday next, at 8.30 p.m., Professor Harvey Littlejohn will read a paper on the micro-spectroscope in the medico-legal detection of blood, to be followed by a demonstration thereof. Dr. T. H. G. Shore and Sir Bernard Spilsbury will exhibit specimens.

MESSRS. CASSELL AND CO., LTD., announce for early publication a new book by Sir Frederick Treves, entitled *The Elephant Man and Other Reminiscences*.

PROFESSOR FINKET has been elected President of the Belgian Royal Academy of Medicine.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Attilogy, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, Mediscera, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: Macillus, Dublin; telephone, 4757, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: Associate, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

DR. HENRY WALDO (Clifton, Bristol) asks for advice as to the most suitable parts of England for a male patient, aged about 50, to live, with more or less persistent anaemia.

#### INCOME TAX.

"J. C." has been assessed separately for his remuneration as coroner.

"We understand that the Board of Inland Revenue have no objection to salaries for such appointments being included with the general earnings of a medical practitioner in one sum for assessment under Schedule D; "J. C." might point this out to the local inspector. Allowances made voluntarily by relatives are not chargeable to tax on the recipient. Allowance can be claimed for the children (on the form of return or subsequently), provided they are attending recognized educational establishments for whole-time instruction. Our correspondent does not say at what sum his general earnings were assessed, and we therefore cannot deal with the other points to which he refers.

### LETTERS, NOTES, ETC.

#### TENNIS ELBOW.

DR. J. G. M. MOLOSY (Truro) writes: At the end of September, 1921, I returned from a month's holiday with a very acute tennis elbow. The pain and tenderness were typical. To lift a loaf of bread with my hand pronated was almost impossible owing to pain. The only treatment was rest, and I refrained from playing badminton during the winter. I started this year's tennis season in fear as my "elbow" was still rather tender. The condition I attribute solely to the fact that as I thought my racquet handle in 1921 was too thin for my grip I put some strapping and two layers of gauze bandage over it. I removed this artificial thickening at the beginning of the 1922 season, and have had no further trouble. Eventually, for the first three weeks of last September I played every day at least five or six sets. My arm is now perfectly well, no pain or tenderness.

#### A QUESTION OF PIGMENT.

CHANCE, aided by circumstance, has made us acquainted with the existence of *The Shakespearean Quarterly*, printed in Sydney, which reached its fourth number in October. The circumstance which has brought us this good fortune is that the number contains a paper by Dr. Frank A. Nyulasy of Melbourne, who is exercised by the question whether Othello was brown or black, arab or negro, and by other doubts. Professor A. C. Bradley is quoted as asserting that the stage tradition down to 1814 was that Othello was to be played as almost quite black, but it may be questioned whether Bradley's statement is correct. At the present time the stage tradition is that Othello should have a full brown complexion, not black, but nobody exactly knows how far this tradition goes back. It is really rather amusing how easily many of us get excited about a question like this, which is, in truth, insoluble. We are really trying to satisfy ourselves as to the picture Shakespeare had in his mind, for doubtless he had a picture of the Moor, since Shakespeare's visual memory was very strong.

#### A CATGUT HOLDER.

MR. A. P. BERTWISTLE, M.B., Ch.B., Resident Surgical Officer, General Infirmary, Leeds, writes: The need for a simple catgut holder is felt by all doing casualty work. A glass jar with an internal flange is selected and a strip of plate glass perforated in

the centre is cut, the length equal to the diameter of the jar. The perforation in the strip is plugged with rubber tubing and through it the ends of several strips of catgut are drawn, the catgut being lightly rolled on glass reels. The plate is now wedged in position with the aid of rubber tubing. The design permits of a suitable length being withdrawn, the rubber preventing the end from slipping back.

#### PREVENTION OF VENEREAL DISEASE.

DR. C. LUXDIE (S. Africa) writes: "G.'s" comments (October 14th, 1922, p. 706) on Mr. Herbert Caiger's letter about the "Radical prevention of venereal disease," seem to me needlessly alarmist in nature. Mr. Caiger is very explicit about the slowness of his proposed method, as is made very clear when he admits, in spite of his results on the improvement of morals between the first and the twentieth centuries, that the results are disappointing and inadequate to modern moralists (italics are mine). If nearly 2,000 years of the method upheld produce only disappointing and inadequate results in 2,050 years, I think we may safely take it that a geological aeon will be required to accomplish what is desired; so sweaters and other oppressors of their fellow men may sit at ease and fear no revolutionary turn of events to sweep them untimely to the warmer climes that they anticipate. What works at the rate of natural evolution will work no revolutionary changes in human affairs.

If Mr. Caiger had included among the very inadequate other methods the one which is equally inefficient from an ethical point of view, but which is the most efficient deterrent to the individual sinner, I should certainly have expected an outcry, in spite of the excellent practice that the adoption of such a method would provide for young surgeons, and the restoration of balance that it would effect in the coming generation between the progeny of the survivors of the unsyphilized who were killed wholesale during the war and the syphilized who were so safe from danger during long periods at the base. Not every one had such a long time of duty (not as one promoted from the wards to the staff as so many were) in military venereal hospitals as myself, so that I do not expect even such even-handed justice as the equalizing of the chances of posterity to reconcile many to such drastic treatment; so the equalizing must be left to the disease itself with, unfortunately, much more involvement of the innocent than the deliberate administration of justice would do. I am afraid my long spell of safe and inglorious duty among the "blessés de Venus," as a French officer once described them to me, would make me more easily reconciled to such an adjunct to Mr. Caiger's preventive method than most would be. It is a simple little operation that has even been done with a string. It certainly might save much suffering if scientifically carried out. Further, it would postpone the time anticipated by Stefansson (in his articles contributed to *The World's Work*), when the world's food supply will run short and either plague, famine, or a still more dreadful war than the last will be necessary to adjust the population whose overstocking could have been so easily prevented surgically.

#### COLLOIDAL GOLD FOR THE LANGE TEST.

##### Correction.

DR. TEMPLE GREY calls attention to a misprint in his memorandum under the above heading printed in the JOURNAL of December 9th, 1922 (p. 1120). In the third line of the small type, for "1 c.cm. of AuCl<sub>3</sub>NaCl" read "1 c.cm. of a 1 per cent. solution of AuCl<sub>3</sub>NaCl" (in aq. dest.).

#### A DISCLAIMER.

MR. HAROLD BURROWS, F.R.C.S. (Portsmouth), writes: As the author of a book, designed solely for medical practitioners, on *Mistakes and Accidents of Surgery*, may I have the hospitality of your columns in order to disclaim any connexion with the notices of that book which have appeared in the public press? I wish it to be known that I have not granted any interviews to journalists, nor have review copies of the work been forwarded to the lay newspapers.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 34, 35, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 15.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

## A British Medical Association Lecture ON SOME PRACTICAL DIFFICULTIES IN OBSTETRICS AND GYNAECOLOGY.\*

BY

COMYNS BERKELEY, M.D., M.Ch., M.A.CANTAB.,  
F.R.C.P.LOND.

OBSTETRIC AND GYNAECOLOGICAL SURGEON TO THE MIDDLESEX HOSPITAL;  
SURG. ON, CHELSEA HOSPITAL FOR WOMEN; SENIOR OBSTETRIC  
SURGEON, THE CITY OF LONDON MATERNITY HOSPITAL.

### RUPTURE OF THE PERINEUM.

If sufficient care is not taken, particularly when attending a woman in her first labour, to ensure that the occiput has escaped under the pubic arch before the birth of the head by extension is allowed to occur, a tear of the perineum will almost certainly result, and this is not infrequently fairly severe. Now tears of the perineum should always be sutured, and, although it may seem superfluous to say this, yet one has often heard a doctor state that he never inserts any sutures unless the laceration is a bad one. A wound in such a position, however, increases the risk of bacterial infection; it may slough, with resulting septic intoxication, and, inasmuch as it is an indication that some part of the pelvic floor has been injured, it is partly responsible for prolapse of the uterus should this occur later on.

Not only should all tears be sutured, but they should be efficiently sutured, and this entails a thorough examination of the injury. I do not think I shall exaggerate if I say that many doctors are satisfied with an inspection of the base of the perineum as it stretches between the vulval orifice and anus, and, if the skin in this situation is intact, assume that the perineum is not ruptured; or, if a laceration in this situation can be seen, are satisfied that this is the only part that requires attention.

Now, apart from the risk of sepsis, a mere laceration of the skin and immediately subjacent tissues between the vaginal orifice and the anus is not of great moment. If, however, in all cases the patient be properly examined it will be found that in certain of them the anterior face of the perineum, covered by the lower inch or so of the posterior vaginal wall, is torn, and it is this injury that plays a part in prolapse of the uterus, meaning, as it does, that the levatores ani are torn or unduly stretched. After labour, therefore, every patient should be placed in the lithotomy position across the bed and the labia separated; with the aid of a good light the practitioner will then be able to determine accurately the extent of an injury should it be present, and if so to treat it efficiently by inserting deep sutures. It is impossible to make a proper examination with the patient in the left lateral position. That this is often deemed to be sufficient is evident by the fact that one is not infrequently called upon to perform plastic operations on the vagina in cases of prolapse in which the skin between the vulval orifice and anus is perfect, but in which a proper examination will disclose that the perineal body has been badly torn and has not been repaired.

### OCCIPITO-POSTERIOR PRESENTATIONS.

The most severe ruptures of the pelvic floor are due to the use of the forceps, as a first choice in treatment, in those third or fourth vertex presentations in which the birth of the head is delayed because the occiput has rotated backwards. What is the reason for such unscientific treatment? My experience tells me that either the doctor does not recognize this complication, or, if he does, is usually unacquainted with the correct way to treat it.

At the commencement of labour there should not often be much difficulty in detecting an occipito-posterior presentation if a routine abdominal examination is made. This diagnosis can be confirmed by vaginal examination when the cervix is dilated sufficiently to allow the presenting part to be palpated easily. Unfortunately such routine examinations are not by any means universal. If, as rarely happens, such examinations are postponed until there is an obvious delay in the birth of the head, it must at once be admitted that a correct diagnosis is not at all an easy matter, even for one with special experience. When the membranes have ruptured and

the uterus is strongly contracting an abdominal diagnosis is very difficult, whilst the large caput succedaneum prevents efficient palpation of the presenting part by vaginal examination.

I think it is a fair statement to make that in very many of these cases the doctor rightly comes to the conclusion that the delay in the birth of the child is due to disproportion between its head and the pelvis of the mother, but that he remains ignorant of the cause of this disproportion until, having applied the forceps more than once and finding that they keep slipping, he at last does what he should have done hours before—that is, make a thorough examination.

If the head is presenting as a third or fourth vertex one should be able to feel in front, early in labour, knobs due to the arms and legs, instead of the usual broad back. The head has not entered the pelvis as far as it should have done, the foetal heart, if heard at all, is heard out towards the flank, and there is often a history, which is very suspicious, of premature rupture of the membranes. Later, when the cervix is sufficiently dilated, the sagittal suture can be felt in one or other oblique diameter and the anterior fontanelle can be felt, showing that the head is not properly flexed. With such information, if it is found that as time goes on the head is not descending so rapidly as it should do in spite of good uterine contractions, it is at once possible to visualize the cause and the appropriate treatment can then easily be applied. But supposing the doctor is not called in until the second stage of labour has become prolonged, or has allowed it to be prolonged before making his examination, he can, in spite of the large caput succedaneum obliterating the sutures and anterior fontanelle, still arrive at a correct diagnosis by passing his hand up the side of the head and feeling in which direction the pinna of an ear is pointing. In first labours an anaesthetic must be given for this examination.

The causes of delay can easily be understood. As the head is incompletely flexed the occiput rotates back below the sacral promontory and the fronto-occipital diameter of 4½ in. has to pass through the vaginal orifice, whereas when the occiput has rotated forwards and the head is properly flexed a diameter of 3½ in. distends the orifice. Again, the occiput being behind, the greatest circumference distending the vaginal orifice is 14 in., instead of 12 in. when the occiput is in front.

On the other hand, the doctor may have diagnosed correctly the misplacement but does not treat it scientifically; the result will be just the same as if he had not made a diagnosis—namely, a very badly lacerated pelvic floor, often into the rectum. This means that frequently a recto-vaginal fistula results, and in due course prolapse of the uterus is nearly certain to occur. But this is not all; the child is often born in a condition of white asphyxia or is delivered dead, or dies soon after delivery from intracranial haemorrhage due to the severe pressure of the forceps.

The treatment, therefore, is with the internal hand to flex the head by pushing up the forehead and to rotate the occiput forward. Such a procedure, with the patient anaesthetized, unless labour has been very prolonged, is not difficult if care be taken when the head is being rotated with the internal hand to turn the anterior shoulder to the front with the other hand on the abdomen. The neglect to turn this shoulder will result in the head being twisted on the neck only, and when it is released it will return to its original position. If it be found impossible to rotate the occiput forward by such means success may still be obtained by passing the internal hand above the head and then seizing the shoulders and rotating them. After the head has been rotated the child can be delivered by the forceps.

There remain those rare cases in which, owing to the strong pains and undue prolongation of labour, the head of the child has been driven down so tightly into the pelvic cavity that its rotation is impossible. If the child is dead it should, in the interest of the mother, be delivered by perforating its head. If the child is alive, there remains only delivery by the forceps. The proper forceps to use are the axis traction, because the fact that the handles are free to move in any direction will at times allow the occiput to rotate even at the last moment; serious injury to the mother will thus be averted.

### THE OBSTETRIC FORCEPS.

I often think that, in the case of womankind, this additional supplication should be added to the Litany: "From the obstetric forceps and uterine curette, Good Lord, deliver us." They are the two most dangerous instruments which any doctor may legitimately employ in the practice of his

\* Delivered before the Northamptonshire Division of the South Midland Branch on November 14th, 1922.

profession. By far the most common indication for the use of the forceps is unusual delay in the birth of the child, and in the vast majority of cases when the forceps are used it is for such a purpose.

Now, strictly speaking, in such cases the forceps should only be used when it is certain that, if the uterine contractions were only strong enough, Nature would herself deliver the child. Hence it comes about that the forceps, when used legitimately, are in most cases employed when the patient is suffering from the condition known as a "sluggish uterus."

No woman with a contracted pelvis should be delivered by the forceps in whom, if only the pains had been strong enough, the head could have been moulded and pushed through the pelvis. It may be taken, therefore, as a maxim that if, in the presence of strong uterine pains and a normal presentation, allowing plenty of time, the child is not born before the condition of the mother warrants interference by the doctor, then the case is not suitable for delivery by the forceps.

It is a fact that the forceps are used much more frequently in private practice than in the labour wards of a hospital, and this in spite of the fact that the percentage of difficult cases is greater in hospital than in private practice. The reasons for this are not far to seek. In the first place the general practitioner is apt to be worried by the relatives of the patient if the child is not born as soon as they think it should be. In the second place—and here its use is if anything more reprehensible—the instrument is employed to save his time.

Delivering the child with this instrument before the os is properly dilated is responsible for a large amount of misery to many women, and every now and then is the direct cause of their death or that of their children. Now, it is an aphorism that the forceps should never be applied and the head delivered until the os is fully dilated, except in rare cases, and then only when this canal has been dilated with the gloved fingers. There are some who do not hesitate to use the forceps before the os is sufficiently dilated, relying on the forceps to do this. In not a few instances I have known the uterus by such a procedure torn right into the broad ligament, with a resulting haematoma, on occasions followed by suppuration, and twice I have known a patient bleed to death from rupture of the uterine artery. Fortunately such catastrophes are rare because the softened cervix allows itself to be stretched. Quite commonly, however, the cervix is split up to the vaginal fornix, and this is not realized at the time. Moreover, even apart from such a laceration, by the time the forceps have stretched the cervical canal sufficiently to allow the head to pass, the cervix has been pulled down so much that its attachments, especially the lateral cervical ligaments, become stretched or torn and the integrity of the pelvic floor is severely damaged, with the inevitable result of prolapse of the uterus later on. Only last week a patient with a normal pelvis, and in whom a normal vertex had presented, was admitted to hospital with the history that delivery by the forceps had failed. On examination the os was found to be only partially dilated, and the head of the child had escaped through a laceration of the uterus in its lower uterine segment into the abdominal cavity.

Now let us turn to the use of the forceps when there is a disproportion between the head of the child and the pelvis of the mother. I will pass by the cases due to malpresentation, since these should be rectified, and also those in which the head of the child is larger than normal, since these are quite rare, and, moreover, the treatment is the same as when the pelvis is smaller than normal. From time to time I meet one of my old students at the hospital, and every now and then one of them will tell me with pride how, after a tremendous struggle and with the aid of one of his feet against the side of the bedstead, he has been able, by pulling with all his might, to deliver the child. Not much of a testimonial to my teaching, you will say! Inquiry as to the child's health will elicit the information that unfortunately it was born dead or died a few hours after delivery—the death being due, of course, to intracranial haemorrhage. The unscientific use of the forceps in this connexion is responsible every year for a large number of foetal deaths, some maternal deaths, and much maternal morbidity.

In such cases of disproportion, however, it frequently happens that the pains are not very strong, and it will be asked in what circumstances can the practitioner justifiably use the forceps. The head may be arrested above the brim, in the brim, or in the pelvic cavity. If the head is movable above the brim the forceps are absolutely contraindicated.

If the head is delayed in the brim a most careful examination should be made, under anaesthesia, of the relative sizes of the head and the pelvis. If no malpresentation is present, and if, in the case of a flattened pelvis, the biparietal diameter has passed through the brim, it is evident that the disparity in size is not great; if in the case of a generally contracted pelvis the head is held fast, additional time should be given to Nature for the head to mould, when as a rule Nature's efforts will suffice. The general condition of the patient should be treated and the forceps only applied when the condition of the mother—as shown by the pulse rate and the fact that she is not sleeping between the pains—demands interference. The necessity for such a warning is evidenced by the fact that a strong pull will be necessary, and, however careful the practitioner may be, lacerations of the perineum are likely to result, and certainly the head of the child will be unduly compressed, and very likely for some time. If the head is delayed in the pelvic cavity and does not advance with the pains or recede in the interval, and if the vagina is oedematous and hot and dry, the forceps again are contraindicated. I need not further discuss the care that should be exercised in the application of the forceps. It seems superfluous to mention that the blades should be applied inside the uterus if the head has not yet passed through the cervical canal, and they should be in contact with the head. And yet I know of two cases in which the forceps were forced into the broad ligament, the lower uterine segment grasped as it was in contact with the head, and by strong traction torn right off the upper uterine segment.

#### CURETTING.

The operation of curetting is extremely common, and is constantly being abused, employed as it is from time to time for most of the conditions which may be attributed, without any adequate reason, to local disease of the uterus. In a large number of cases the operation does no good, whilst in some, from time to time, it is followed by such disasters as intra-peritoneal haemorrhage, pelvic haematoma, pelvic cellulitis, salpingitis, and even death. The operation of curetting, as too often practised, consists in removing the mucous membrane lining the body of the uterus. Such a procedure presupposes that this lining is diseased, but in many cases it is quite healthy.

Let us review the sort of cases for which curetting is most frequently employed. In the first place we will take leucorrhoea, because this is the commonest symptom for the relief of which the operation is performed. The normal discharge escaping from the vagina is sticky, from the mucous secretion of the cervical and Bartholin's glands. Just before menstruation and during pregnancy there may be such an excess of discharge as to cause a certain amount of vulval discomfort and to soil the underlinen. A leucorrhoeal discharge in excess of this, and at other times sufficient in quantity to necessitate the use of a diaper, is abnormal and should be treated. Curetting the body of the uterus, however, in such cases will do no good at all, and the doctor may well be disappointed. The discharge from the corporeal mucous membrane is clear and watery, and, although women suffering from chronic endometritis may have severe leucorrhoea as well, most of the discharge is due to a chronic inflammation of the cervical mucous membrane, and as this is seldom treated efficiently disappointment results.

The cause of excessive leucorrhoea is a chronic inflammatory condition of the cervical mucous membrane. Such a condition is often found in women who have had children, but unmarried women who have not had children not infrequently suffer from it. The endometrium of the body is not as a rule affected, the only symptom being leucorrhoea. When a vaginal examination is made quite commonly an erosion is detected.

Now, the operation of curetting for leucorrhoea, as generally performed, consists in removing the fairly thick, loosely attached soft mucous membrane of the body of the uterus, whilst the thin mucous membrane of the cervix which is firmly attached to the muscle, and in which are embedded the racemose glands, is not curetted at all, or so perfunctorily that the diseased glands remain. When the only complaint is leucorrhoea and an operation has been decided upon, there is no need to curette the body of the uterus; it will not do any good and it may do harm. The cervical mucous membrane, however, should be thoroughly scraped with a sharp spoon, and the erosion if present should be similarly treated.

Another common complaint for which curetting is performed is congestive dysmenorrhoea; this is due to an additional

flow of blood to the genital organs, which causes increased tension, stretches the nerves, and so gives rise to pain more or less severe. Removing the mucous membrane of the body of the uterus cannot prevent the additional flow of blood naturally taking place prior to menstruation, neither can it remove the nerves or interfere with their distribution. Hence the operation is an unqualified failure. Why, then, is it so commonly employed? The answer must be that in some cases it is followed by alleviation of the menstrual pain; but in these cases the pain that is relieved is not due to the congestive dysmenorrhoea, but to the spasmodic variety with which it is in such cases associated. Moreover, even then it is not the curetting that relieves the patient, but the dilatation of the cervix antecedent to the curetting, so that the latter is superfluous. It is obvious, therefore, that the disappointment so often associated with the operation when performed for dysmenorrhoea could be obviated if doctors would only take care in diagnosing which variety of dysmenorrhoea their patient is suffering from.

Another class of case for which this operation is performed is that of excessive uterine haemorrhage. Such diseases as chronic endometritis, mucous polypi, and subinvolution, with or without retained products, are successfully treated by this method. In the absence, however, of a careful local examination and a full consideration of all the circumstances, the uterus is quite frequently curetted for haemorrhage due to conditions in which it can do no good, and may perhaps do harm. Among these I may mention excessive bleeding due to an abnormal function of the endocrine glands, fibrosis of the uterus, salpingo-oophoritis, and fibroid tumours.

Lastly, curetting is often employed in cases of sterility, without the doctor certainly ascertaining that it is not due to some condition of the husband which renders him sterile. I should not be surprised to hear, in the majority of cases in which curetting has been employed for sterility, that the seminal fluid of the husband has never been examined. If one comes to think of it, however, considering that it is calculated that in 10 per cent. of all cases of sterility the fault is on the husband's side, what a criminal thing it is to subject a wife to the discomforts and dangers of such an operation before ascertaining that the testicular secretion of her husband is normal. However, in the absence of local disease, curetting for sterility is on occasions dramatically successful. But here again it is a question whether the actual curetting, in most cases at any rate, is the cause of the success. More probably it is due to the dilatation of the cervix, in spite of the fact that many authorities consider the curetting to be an essential factor.

Apart from the indications I have given, the cervix should certainly be dilated, whatever the age of the patient, in those cases in which no local disease can be found and yet the patient is suffering from irregular bleeding; although in the case of young women it may be justifiable to try a short course of medicinal treatment first on the chance that the symptoms will be cured.

When the cervix is dilated, retained products of conception, polypi, small submucous fibroids, or malignant disease may be discovered; whilst in the absence of any evidence of such disease some mucous membrane can be removed for microscopical examination, when, especially in elderly women, early malignant disease or senile endometritis may be discovered, the latter being well treated by a thorough curetting.

The operation of curetting is generally regarded as easy and safe, though I have known operators of great experience fail to dilate the cervical canal, and be able to enlarge the internal os only by incising the cervix on each side until this appears in view. Safe the operation never is, and gynaecological surgeons, even of large experience, do not care much about performing it.

There are special accidents connected with each of the two parts of the operation which the operator, unless he is forewarned, may fail to detect. I will not discuss the risk of sepsis, though it is a very real one, since everyone who does any operating should have full knowledge of it. There remain laceration of the cervix, perforation of the uterus, and excessive bleeding.

To curette the uterus the cervix must be dilated. Before inserting the dilators it is necessary to know the exact position of the uterus; failure to recognize this has often led to perforation of the anterior wall of the uterus when the latter has been displaced backwards. Yet doctors quite frequently start the operation without making a bimanual examination or passing the uterine sound. The next danger

is concerned with the dilatation of the cervix. It is probable that in all cases in which the cervical canal is dilated sufficiently to insert the index finger for purposes of diagnosis some of the muscle fibres in the neighbourhood of the internal os are lacerated. At times, however, owing to the rigidity of the tissue and the consequent employment of excessive force, or because of bad technique, the cervix is very badly lacerated. Excessive force can easily be avoided by holding the dilator with the thumb and first two fingers only and resting the wrist against the buttock of the patient. To seize hold of the dilator with the hand, and without any counter-pressure of the buttock, then to press the dilator forward with great force, at times leads to the internal os suddenly splitting, when, before the operator can control it, the end of the dilator shoots forward and the uterine wall is perforated. I have seen this happen more than once.

By bad technique I mean not being sure that each succeeding dilator is inserted at least through the internal os. If the internal os is difficult to dilate it may easily happen that the dilator used is not inserted as far as the previous one. If the operator is not paying particular attention, or is ignorant that such a thing is likely to occur, each succeeding dilator goes in a shorter and shorter distance; in fact, the cervical canal only is being dilated efficiently and not the internal os. When he has passed as many dilators as he thinks necessary the operator in ignorance curettes the cervical canal only; or alternatively, if the operator notices that there is an increasing difficulty in getting his dilators to pass through the internal os, he commences to use undue force. The result is that the muscle fibres in the neighbourhood of the internal os are lacerated, and the point of each succeeding dilator, instead of passing through the os, catches in this laceration and perforates the uterus, commonly into the broad ligament and more rarely into the utero-vesical pouch. In such circumstances the curette has been passed through the laceration and the tissue beyond curetted.

The cervix having been dilated successfully there still remains the danger of perforation. This accident is very likely to happen if the uterine wall is soft, as it is in pregnancy, and this, together with the risk of sepsis, is the reason why most authorities teach that the uterus should not be curetted for retained products in cases of very recent miscarriage. On the other hand, the uterine wall may be the seat of unsuspected malignant disease, into which the curette will sink as easily as it will into a pat of butter. If a flushing curette is being used some of the lotion may be delivered into the peritoneal cavity before the operator is aware of the accident, and fatal results have been reported in such circumstances; if, as should be the practice, a non-flushing curette is being used and the case is a clean one, as a rule the patient does quite well as long as the operation is stopped and a douche is not given. If the case is a septic one, pelvic cellulitis or peritonitis, as the case may be, may result, and I have known deaths in such circumstances. Perforation may also lead to intraperitoneal bleeding necessitating the removal of the uterus, of which I have seen one case.

Sometimes after curetting the bleeding is quite severe, especially in cases of retained products which are rightly curetted some time after miscarriage; in such cases the uterus should be packed. A graver form of haemorrhage occurs in severe laceration of the cervix when the uterine artery or an important branch thereof has been ruptured. In such cases sutures inserted through the lacerated cervix are usually sufficient to stop the bleeding; failing that the artery will have to be exposed and tied either by the vaginal or the abdominal route. More rarely the blood, instead of escaping externally, infiltrates the cellular tissue of the broad ligament, causing a large haematoma, which may spread upwards over the pelvic brim and necessitate the abdomen being opened.

Lastly, occasionally very serious bleeding happens about the tenth to the fourteenth day after the operation, and failure to recognize its cause may lead to a fatal result. It is due to sloughing of the uterine artery, or to the displacement of a thrombus in the torn artery following a severe laceration of the cervix. I have seen such cases in hospital practice, and on three occasions I have been asked to see similar cases in private. On the last occasion the patient was so bad that I had to remove the uterus immediately and resort to transfusion. In this case when the bleeding first started the uterus had been packed on the assumption that the blood was coming from the uterine cavity.

## THE ARTIFICIAL TERMINATION OF PREGNANCY.

Women regard miscarriages or premature labours from different points of view. While some are heartily glad to be free of what they consider to be an incubus, others are so grieved that a serious mental effect may be produced, and if it be the only time they have been pregnant entirely after their outlook on life. Apart, however, from the feelings of the patient or her husband, the medical attendant has certain things to consider. For instance, every year a certain number of deaths are associated with the artificial termination of pregnancy; moreover, such an operation may be followed by much misery from chronic disease of the uterus and its appendages. Further, the practitioner is depriving the nation of a potential citizen, and perhaps—who knows?—of a Shakespeare or a Newton.

There are many conditions in which pregnancy may legitimately be terminated forthwith and without any hesitation; these are for the most part rare, with the exception of molar pregnancy and severe toxæmia, and I do not intend to discuss them. Certain other conditions comprise the majority of cases in which pregnancy is prematurely terminated, and in many instances such a method of treatment is inadvisable or quite unwarranted. These conditions are: bleeding from the uterus, severe vomiting, and certain cases of albuminuria.

It is often very difficult to determine in the case of a pregnant woman who is bleeding whether to empty the uterus or not. Unless the bleeding is so severe that it causes marked symptoms and signs it is no indication that the pregnancy should be terminated, neither is the duration of the bleeding nor the colour of the blood escaping. I have vivid recollections of a patient who bled not a little for five consecutive weeks, commencing when she was four months pregnant. At the end of the five weeks the bleeding stopped, and after a further rest in bed for another ten days I allowed her to get up. The same afternoon, when walking from her bed to the sofa, she had a really furious hæmorrhage which spoilt the sofa and carpet before she could be got back to bed. As she had previously had one Fallopian tube removed for a ruptured tubal gestation, when she nearly lost her life, and had subsequently not become pregnant for four years until she had been cured for chronic endometritis, and as an heir was particularly desired and her husband was approaching 60 years of age, great pressure was brought to bear upon me to give her another chance. Beyond a somewhat free discharge for the next day or two nothing occurred, and at the end of another fortnight I again allowed the patient to get up, and subsequently delivered her at term, with no difficulty, of a child weighing 8 lb.

I feel confident that the uterus in a large number of pregnant patients is emptied because of bleeding when there is no need or justification. The doctor is not always to blame for this; many patients will not tolerate the proper treatment, or their circumstances will not allow them to follow it. Others, in their anxiety to get rid of the pregnancy, do not follow the treatment prescribed, and deliberately by various acts endeavour to hasten the evacuation of the uterus, whilst the patients of a third group or their relatives may be so alarmed at the bleeding and worry the doctor so much that in desperation he empties the uterus. Now unless the bleeding is really dangerous the doctor should be in no hurry to empty the uterus until he is satisfied, by the fact that the uterus is not normally increasing in size, that the ovum is dead. This may mean waiting for a month or more. Moreover, the fact that a discharge is brown in colour is no certain indication that the ovum is dead; such a colour may be due to the fact that the blood has been held up in the uterus, and if allowed to lie in the vagina it may even become offensive.

Of all the subterfuges women invent to get rid of their pregnancy, sickness is the commonest. Morning sickness, or, later in pregnancy, severe vomiting due to neurosis and not toxæmia, may be very difficult to treat, short of emptying the uterus. In such cases many a doctor has been driven to empty the uterus against his better judgement, either from the insistence of the patient or of her relatives, or because the patient refuses or cannot afford to follow the correct treatment. It behoves every doctor, therefore, to be very circumspect when he is faced by such a complication. In the first place, he must satisfy himself that the patient really is as sick as she says, and, secondly, whether the sickness is due to neurosis or to toxæmia. To give an example: I know of the case of a well educated woman in a very good position who, having had three children, was determined not to have a fourth. In due course, therefore, she commenced to

complain of sickness and inability to take any food. That she took but little food at her meals was certain from the observation of those in her company, and that she was constantly being sick was evident from the noises she made and the contents of the receptacles into which she vomited. Her medical attendant never tested her urine, and at last, what with the worrying of the patient and her husband, became unduly alarmed and telephoned for a consultant, who hurried down to the patient and, without any examination of the urine, then and there emptied the uterus. Needless to say, the patient made a splendid recovery. Now as a fact, as reported to me some years later by a friend of hers, the patient had boasted to her how she had tricked the doctors by eating quite good meals in secret and later making herself sick by tickling the back of her throat.

If severe vomiting in pregnancy is not due to toxæmia—and in most cases it is not—it can be cured by placing the patient in an institution away from her friends, taking no notice of her refusal to eat, and supplying her regularly with three meals a day. Unfortunately all patients cannot afford to go into a nursing home, and some may refuse to go into the hospital, so that in the end pregnancy has to be terminated. The presence of albumin in the urine and other evidences of toxæmia is an indication that the vomiting is of the toxæmic type, and such indications will now be discussed.

## ALBUMINURIA IN PREGNANCY.

It is the duty of every doctor to examine periodically the urine of his pregnant patients. By so doing the superintention of eclampsia, one of the most tragic complications of pregnancy or labour, may be avoided. There is also another aspect. Nowadays, what with the ante-natal clinics and the wider diffusion of knowledge generally, it is well known by others than members of the medical profession that the urine of pregnant women should be examined at repeated intervals. The neglect to do so, if eclampsia intervenes, may, as in the instance of a doctor friend of mine, land the practitioner in an action for damages for gross neglect, and sooner than face a public trial of such a nature he may have to pay a large sum to settle the matter.

With the modern biochemical methods of ascertaining the condition of the liver and kidneys at his command, either through the medium of hospital or private laboratories, the doctor has but little excuse if, having discovered albumin in a pregnant woman, he does not have such an examination made. A chemical examination of the blood and urine may be of the greatest value in preventing permanent damage to the patient and also of the greatest value to the doctor in showing him when it is advisable to terminate the pregnancy. Nowadays we do not rely on the amount of albumin and the general condition of the patient so much as on certain tests, which include (1) the estimation of the blood urea, (2) the urea concentration test.

## Estimation of the Blood Urea.

Blood (10 c.cm. or even more) is taken from the patient and tested for the amount of urea it contains. Normally there is in a healthy pregnant woman about 20 mg. per 100 c.cm. If the urea content of the blood is definitely raised, say to 40 mg. per 100 c.cm., it is proof that the kidneys are severely damaged, and an indication that the labour should be terminated.

## Urea Concentration Test.

The bladder having been emptied, 15 grams of urea dissolved in half a pint of water are given. One hour and two hours after this solution has been drunk the bladder is emptied and the amount of urea is estimated in each specimen. If the kidneys are normal the first specimen should contain at least 1.5 per cent. of urea, the second 2 per cent. If lower figures are obtained a renal lesion is to be suspected. Repetition of both estimations after an interval is invaluable, since a rising blood urea with a falling concentration capacity constitute an obvious indication of a progressive lesion.

## PELVIC HÆMATOCELE: RETROVERTED GRAVID UTERUS.

An error of diagnosis, among the most serious I know of with respect to its immediate result, is that of mistaking a pelvic hæmatocele due to extrauterine gestation for a retroverted gravid uterus that is bleeding. I have met with this mistaken diagnosis many times, and have known it to lead to a fatal result.

If we consider the symptoms and signs of these conditions up to a point we need not be so astonished at such a mistake, since the condition may easily be confused unless a most careful investigation is made. In both these complications there may have been a period of amenorrhoea, for the rupture or abortion of a pregnant Fallopian tube does not usually take place before the sixth week of pregnancy, and

may occur as late as the twelfth week, whilst nausea, alteration in the breasts, and softening of the cervix, which are found in intrauterine pregnancy, may also be present in extrauterine pregnancy. In the case of rupture or abortion of a pregnant tube there is bleeding due to the separation of the decidua, whilst a threatened or inevitable miscarriage in a retroverted gravid uterus is not uncommon. In extrauterine gestation a decidua membrane may have been passed, whilst the ovum or part of it may be expelled by the retroverted gravid uterus. In the case of a ruptured or aborted pregnant tube the swelling in the pouch of Douglas is due to the blood which has escaped, whilst the body of the retroverted gravid uterus forms a somewhat similar swelling.

If, then, a case of pelvic haematocoele presents itself to a practitioner he may wrongly assume that he has to deal with a case of retroverted gravid uterus that is bleeding, and he proceeds to treat the patient as follows; and I remember many examples of all three methods of treatment.

1. If the bleeding is not very much, he may endeavour to push up the supposed fundus of the uterus preparatory to inserting a ring pessary with the object of preventing the supposed miscarriage.

2. If the bleeding is severe, he may endeavour to empty the uterus.

3. If the bleeding is slight and continuous, and some substance has been passed, he may come to the conclusion that his patient, having miscarried, is suffering from subinvolution, and think it his duty to curette her.

But suppose the case is one of pelvic haematocoele, what will be the result? In the first case he cannot push up the swelling with the ease to which he is accustomed, and, using greater force, still further ruptures the tube if it is already damaged, or ruptures it if it is aborting, and the woman becomes desperately ill from internal haemorrhage the cause of which he does not identify. In the second case, on dilating the cervix he is surprised to find the uterus empty, thinks she has miscarried, and as a result of his manipulations serious internal haemorrhage may be started. In the third case, if he does not start serious internal bleeding he will think he has curetted in vain, and the woman will still go on bleeding.

Such a mistake can be avoided by a careful consideration of the history and by a thorough and complete examination of the patient. No woman has a tubal rupture or abortion without very severe abdominal pain. As a rule the pain associated with a threatened or inevitable miscarriage is not very marked. Moreover, in those cases of miscarriage in which the pain is bad the bleeding is also marked, the pain being due to the contraction of the uterus as it separates the whole ovum. On the other hand, with extrauterine gestation the bleeding in practically all cases is slight, and yet the pain is very bad. Again, if the patient exhibits the classical symptoms and signs of bleeding, and the bleeding which can be seen is slight, why does she have such symptoms? She must be bleeding internally. However, even here one may meet with difficulty, because at times the bleeding goes on so slowly that the classical symptoms are a long time developing.

Lastly, we have an absolute means of diagnosis at our command. The cervix in a retroverted gravid uterus will be pointing forward—so far forward at times that it can scarcely be reached, and then only with the patient on her back. On the other hand, the cervix in extrauterine gestation is pointing backwards and the whole uterus is driven forward by the haematocoele. Even this may escape notice, but where is the fundus of the uterus? The practitioner must make certain of this; if he cannot satisfy himself without putting the patient under an anaesthetic this must be done. A bimanual examination in the case of a retroverted gravid uterus will disclose the fact that the body of the uterus is absent from its normal position, and in the case of an extrauterine gestation that the body of the uterus can be grasped bimanually and that there is a further swelling in the pouch of Douglas. The correct diagnosis is made and perhaps a fatal error has been avoided.

#### CARCINOMA OF THE UTERUS.

Out of every hundred women who die during the year in England and Wales four die of cancer of the uterus. The uterus is by far the commonest seat of cancer in the female, and more women die of cancer than of consumption.

Without the slightest doubt cancer of the uterus can be cured. The reason why the vast majority of women thus afflicted die is because the disease is not diagnosed until it is too late to operate. Cancer of the uterus is quite easy to diagnose if the doctor uses all the resources at his hand and

of which he is well aware. Therefore, if a doctor has been consulted, the fact that the disease remains undiagnosed cannot in any way be ascribed to ignorance.

Carcinoma of the cervix is, as a rule, quite easy to diagnose because the suspected part bleeds easily, and sometimes markedly, on being touched. On occasions a patient will present herself to the doctor in an early stage of the disease. He finds that the diseased area bleeds rather freely on being rubbed; so do some erosions; there is no apparent growth, and to his eye it looks like an erosion. He therefore treats her for months, and then, as the condition gets worse, sends the patient to hospital with a note that in spite of prolonged local treatment he cannot get the condition to heal. What should that doctor have done when he found the local condition bled so easily? He should have cut a wedge-shaped piece of the diseased area out of the cervix, including the muscle underneath as well as the surface epithelium, and had it examined by the microscope. This small operation is quite easy to perform, and the bleeding, such as it is, can be at once arrested by suturing the edges of the incision with a catgut suture. If afraid to do this, he might have tested the friability of the patch with a blunt probe or uterine sound.

The only symptom that the patient suffering from carcinoma of the body of the uterus may complain of is bleeding. The average age for carcinoma of the body of the uterus is 53—that is, about the time of, or soon after, the menopause. The cause of irregular bleeding from the cavity of the uterus can easily be determined by dilating the cervical canal and examining the interior of the uterus, when, unless the cancer is very early, its presence can at once be detected. Even if the case be very early, so that no friable patches are felt, a microscopical examination of the material obtained by curetting will give the diagnosis.

I am sure that all medical men know what I have just stated. Why do some of them not apply this knowledge? I cannot tell; I know only what I have been told. Patients are admitted into my wards at the Middlesex Hospital almost every month for cancer of the uterus too far advanced for operation. The notes taken out by the house surgeon state: "The patient has been bleeding for many months; she consulted a doctor, who did not examine her and told her the bleeding was due to the change of life." Again a patient is sent up to me with a note from a doctor that she has had irregular bleeding for some time, that he has given her drugs to no purpose, but he has not examined her because he would not know what he was feeling if he did. Perhaps he adds that he had never had any chance of examining patients vaginally when a student, and so has never felt equal to making a diagnosis in that region. The fact that an erosion of the cervix does not improve with local treatment and bleeds every time it is treated does not for a long while strike some doctors as peculiar.

Now I do not mean to assert for a moment that the blame can always be attributed to the doctor; on the contrary, I think in most cases the reason a diagnosis is not made sooner is because the patient does not seek advice sooner. Her reasons for this are threefold. Most commonly she attributes her irregular bleeding to the change of life, this opinion being supported by the views of her female friends and perhaps of those of some nurse or midwife; or she may object to an internal examination; or, lastly, she may think she has cancer and fears to have her thoughts confirmed. The unfortunate circumstance that irregular bleeding may occur at the menopause without any disease of the uterus is indirectly responsible for the death of hundreds of women every year. When irregular or excessive bleeding does occur, however, there is always an interval, of longer or shorter duration, in which there is no bleeding. The lesson to be learnt, then, is that any unusual bleeding, and especially about the time of the menopause, should always be investigated by a thorough internal examination.

By the radical operation cancer of the cervix can be treated at a very much later stage than by any other procedure. I have taken out the cancer figures at the Middlesex Hospital for the last fifteen years, and I find that I have operated upon over 40 per cent. of those admitted. Most of these were advanced cases, and the disease could not have been removed by any other method. Even with such a handicap my absolute cure percentage—that is, freedom from recurrence for five years—is over 30. I leave you to form your own conclusions as to the results that might be obtained if one could only get these cases in an early stage. The importance of the early diagnosis of cancer of the uterus should be strongly impressed upon nurses and midwives. At the Middlesex

Hospital we have leaflets for distribution to female patients containing in simple language the most important facts concerning this fearful scourge.

#### POST-MATURITY.

It must have happened to everyone who has practised midwifery that on occasions he has had a patient who, by the usual methods of reckoning, has gone beyond term. Such an event not only causes worry to the patient and her relatives, and additional expense because of the nurse, but it may also be a source of much anxiety to the doctor, who in the end has perhaps to attend a difficult labour, followed in many instances by death of the child. The following points are of interest:

1. Post-maturity may be recognized by the presence in the child of excessive length, weight, ossification, and an easy separability of its dura mater.

2. It is probable that spermatozoa cannot live longer in the genital canal than ten days.

3. Although the time between the first day of the last menstruation and delivery, and that of insemination and delivery, can be calculated, that between impregnation or fecundation and delivery cannot within ten days.

4. There are undoubted dangers both to the mother and the child when pregnancy is prolonged beyond its normal time. These dangers are mostly concerned with the difficulty in the passage of the child.

The correct treatment when the practitioner thinks that the child is post-mature is to induce labour. How is he to arrive at such a diagnosis?

1. By noting any prolongation of pregnancy beyond the expected date of delivery, as calculated from the first day of the last period.

2. By a careful ante-natal supervision of his patients, noticing particularly, in the absence of uterine contraction, the ease with which the head of the foetus is passing into the pelvis in a primi-gravida or can be pressed into the pelvis in a multipara.

3. If an allowance of ten days be made over and above the date selected for the day of delivery it may safely be assumed that after this the pregnancy is post mature, due regard being paid to the relation of the foetal head to the mother's pelvis.

4. With this information, therefore, the doctor may justifiably induce labour 290 days after the first day of the last menstruation, and, indeed, many authorities think that he should do so.

#### HOT-WATER BOTTLES.

Burns from hot-water bottles are not as uncommon as one would think. The late Dr. F. J. Smith stated that he knew personally of 80 cases.

As a working rule never allow a hot-water bottle to be placed in the bed of a patient recovering from an anaesthetic, not even if it is surrounded with blankets, because in such a case the patient may be restless and kick the blanket off, when the exposed hot-water bottle may burn her. If, however, it is considered essential, because of shock, to place protected hot-water bottles in the bed, a nurse should be directed to stay by the side of the patient until she has regained consciousness to ensure that she is not left alone. If these precautions have not been exercised, burns may result which take months to heal and then only with dreadful scarring.

I introduce this subject to warn you that even with this knowledge you may be let down owing to the carelessness or disobedience of the nurse.

A friend of mine operated upon a patient. The operation was a very severe one, and he deemed it necessary to give her an intravenous infusion, and as he could not expose the vein in one arm he had to cut down on a vein in the other. The patient, who was in a nursing home, was put back to bed and was frightfully burnt on one buttock and foot with hot-water bottles. Neither the patient nor her husband appears to have been very inquisitive, and the doctor, therefore, did not feel called upon to discuss with them the exact state of affairs. At the end of fourteen weeks the husband said, "Don't you think that those wounds you made on the buttock and leg, which have been so septic, would heal better at my own home?" My friend then discovered that the owner of the nursing home had told the husband that the surgeon had made wounds on both arms and in two places on the leg to inject saline into the veins, and that the wounds on the buttock and leg were larger because the blood vessels could not be found. This was more than my friend could stand, with the result that when the husband was enlightened he refused to pay the expenses of the nursing home. The owner of the home then brought an action to recover the money; the husband brought a counter-claim for damages, and the matter was settled out of court, the husband being paid £500 and costs.

I remember the case of a lady from whom I removed with the greatest difficulty a very adherent ovarian cyst. There was some very free oozing from the raw surfaces left, and no bleeding point could be secured. I therefore had recourse to the method of

temporarily packing the pelvis with swabs wrung out of boiling water. Three days later I visited this patient in the absence of the doctor and with his consent, and discovered to my horror that her buttock and leg had been frightfully burnt with hot-water bottles. The nurse, of course, had to own up, but begged me not to tell the doctor, saying that he might not employ her again if she did not tell him herself. Foolishly I agreed. I heard nothing more of the patient at the time, and was a little disappointed that the doctor had not written to me, because the operation as a surgical exercise was a great success, and it was the first time this particular doctor had given me a case. Some years later a relative of the patient consulted me; told me that her relative's leg was frightfully scarred. Expressing surprise and inquiring how this accident had arisen, the answer was, "Why, don't you remember, it was due to your pouring all that boiling water over her." I asked who said this, and was told the nurses. I then had no hesitation in telling her the true facts. Naturally I at once wrote off to the doctor, from whom I had never heard again, and he replied that the nurses had told the patient that I had had to use boiling water to stop the bleeding, and when wringing out the swabs had spilt the water all down her side. Further, the doctor was kind enough to add that he had thought it wiser to let the blame rest on me because I could be excused in an endeavour to save the patient's life, whereas the nurse could not be excused, and the husband, if he had known the true facts, would have been certain to have brought an action for damages against the nurse; and he, the doctor, hated law suits!

## THE DIAGNOSIS OF INDEFINITE MASSES IN THE BREAST.

BY

DUNCAN C. L. FITZWILLIAMS, C.M.G., CH.M., F.R.C.S.,  
SURGEON, ST. MART'S HOSPITAL, LONDON.

THE diagnosis of small indefinite masses in the breast presents such peculiar difficulties to the medical man, right diagnosis carries with it such advantages, and wrong diagnosis or unnecessary delay such awful penalties to the patient, that the subject is well worthy of consideration.

In early cases of lumps in the breast it is curious, but true, that though the question, Is it a new growth or is it an inflammatory mass? always arises in one's mind, the smaller the mass is the more one is inclined to put it down as inflammatory. Malignancy is associated in our minds with something sinister and threatening. A small and apparently harmless mass is acquitted merely on account of its small size. This is of course quite wrong; malignant growths must all begin small, and then is the right and most favourable moment for their extirpation; that, indeed, may be the only time at which a cure can be guaranteed. But how many small malignant growths do we operate upon, and how many large ones? The proportion is not more than one in six.

It is widely recognized that if carcinoma is removed early, especially in an organ like the breast, where such a large part of the lymph field is easily accessible, the very best results may be achieved. The difficulty is to decide what is early removal, and how it is to be effected. That difficulty I wish chiefly to deal with.

At the same time it must be recognized that we are not dealing with the constant factor of a machine, but with the vagaries of human nature, with those peculiarities of the human mind, with those prejudices inborn centuries ago, and those leanings which we can only explain by saying that they are second nature. We have all heard of cancer cures—the violet-leaf cure, the cure by turpentine, and by escharotic paste, not to mention some of the older ones; then lately x-rays, then radium, then selenium, and now back again to x-rays, and larger and more expensive instruments. Wait! these will go like their predecessors, and will be succeeded by some treatment just as effective or ineffective as you may be pleased to term it. Explanations are useless. Each of these methods not only claims its cures, but each can, I know, produce them; people live after each of these treatments for ten, fifteen, and twenty years in the case of the older methods, and the modern methods and future ones will, I am quite sure, afford similar instances. Each holds out just sufficient encouragement to lure on and, I am afraid, to delude the practitioner into thinking that at last the cure is about to be discovered.

Investigations and experiments should and must continue; I should be the last to decry them. But we, as a profession,

\* A paper read before the Chelsea Clinical Society.

are so prone to rush after every goose long before it flies, crying out so loudly that it is a swan, that a note of warning must be sounded. We are only yet at that stage where, alas! in the vast majority of cases it is the knife, and only the knife, on which we can rely with any certainty. That is the only method upon which we have relied for the last two hundred years. All other methods change constantly; each is said to be successful—why does it fall into disrepute? I think perhaps its success may possibly be fanciful, and due not to the cure, but to the well recognized vagaries of the disease. I believe the same thing will happen with the methods now employed.

Why is it that human nature, especially female nature, fears the knife? You may use an *écraseur* or a cautery, if you like, to do an incomplete operation, but a complete and clean one by the knife is often objected to; and yet for every case receiving benefit by any other means a hundred receive it from the knife. Again, why is it that the knife is refused in early cases, when it is most useful, and resorted to after the waste of so much time that its success is a matter of conjecture? Why is it that human nature prefers a cure by some unorthodox means? Why is it that Naaman the Syrian was wroth and wished Elisha "to come out and strike his hand over the place and recover the leper," instead of doing what the man he had come so far to see told him to do? Human nature is the same to-day as it was then—it still craves for novelty.

In dealing with tumours perhaps it is not recognized sufficiently clearly that the vast majority are malignant. It is computed that 80 to 85 per cent. of tumours of the breast are malignant, and at most 15 to 20 per cent. are innocent, or innocent in their early stages. I do not think that these figures are entirely accurate, as they are collected from records, and it must be obvious that many small and apparently innocent lumps such as we deal with in the out-patient department will have no records at all. But still, if we take 70 per cent. malignant and 30 per cent. innocent we shall be within the true figures.

That means that a lump in the breast, however small, is more than twice as likely to be malignant as it is to be innocent. This is a point which needs emphasis to bring it home to us. It is one of the most difficult things in practice to imagine that a lump, however small, is twice as likely to be malignant as innocent; we are always ready to acquit it on size alone. Then one must bear in mind that there are a large number of cases which we admit are innocent to begin with, but which later take on malignant characters. They do this in two ways—either the character of the growth changes and becomes malignant, or a malignant growth starts in part of a purely innocent growth, such as a cyst wall. To begin with these must obviously have all the symptoms and characters of innocence.

Now if I ask, What is the difference in character between an innocent and malignant growth? you will at once begin to say adherence to the skin, to the deeper structures, glands in the axilla, retraction of and perhaps discharge from the nipple, shrinkage of the organ, etc.—these are the characters with which we associate malignancy, and the absence of these characters denote innocence. The presence or absence of a tumour felt with the flat of the hand, which used to be, and is even now, so insisted upon, is of course quite fallacious. A large malignant growth will of course be felt, but an early and a small one will be just as imperceptible as a chronic mastitis, in which indeed it is very often embedded. I do not, however, intend to go into these characteristics, but rather to deal with the subject in a different manner and ask, What is the meaning of all these characters that we take to be malignant? Is it really true that absence of these characteristics veritably denotes innocence? and we realize at once that the answer is "No." After a moment's reflection we realize that these characteristics denote nothing more than spread, and, pursuing this matter to its more logical conclusion, spread means that much time has been lost before a diagnosis has been made. To extirpate a growth we have to go outside all areas of spread—that is admitted. Why, then, do we wait deliberately till spread has occurred before we arrive at a diagnosis?

I now invite you to accompany me in imagination to the out-patient department. A healthy-looking woman of 50 complains of a lump in the breast which her doctor has seen six months previously and told her was nothing. She now shows a breast with scirrhus written large across it. There is a temptation to abuse the doctor for not sending her to the surgeon for advice sooner, and I have even heard very severe

comments made upon such behaviour to the students. But wait—the very next case which comes up is a woman of the same age who says she has shown her doctor something in her breast, and he has sent her up for advice. On examination there is a small indefinite mass, not adherent to the skin or underlying structures, lying far from the nipple, so that there is no suspicion of retraction, there are no glands in the axilla, there is nothing to point to any cause whatever. On you now rests the responsibility. What are you going to advise? It is often extremely difficult to refrain from giving much the same advice as the doctor you were quite ready to blame a moment ago. You might quite well say, "This is nothing, my good woman, do not worry your mind about it; just come up and see me in a month's time," and think you were justified in doing so. Two or three months may pass without any very obvious change, and then the woman might neglect to come, thinking that it was not very important, as no operation was suggested—for to her an operation is the only important association she has with a lump—and that she need bother no further. Four, six, or eight months might quite well elapse before you see her again, and then the diagnosis may be as easy as in the first case we supposed. Spread has been going on slowly all the time, and the comments you were ready to pass on others may be as justly applied to yourself. You missed the opportunity offered you the first time of carrying out an investigation which would have placed the matter beyond the region of doubt at a time when, if it proved to be malignant, success was almost certain, while now, six to eight months later, it is very problematical.

But while making every excuse for the doctor who has failed to make certain in the early and doubtful stages through which every malignant growth must pass, there are certain cases we all know in which blame may rightly attach to the medical man. There is the careless man, always in a hurry, who never makes a thorough examination—you cannot alter him. Then there is the stage through which we all naturally pass, of non-experience, that rights itself with time. And lastly, and worse than all, there is the too fussy man who knows everything—he alone can assure the patient that "it is nothing." He, curiously enough, is almost always believed implicitly; perhaps the patient wants to believe him. If any doubt is raised he will put in a hypodermic needle, and if he succeeds in drawing off some clear fluid from a mastitic cyst will say, "Now what did I tell you? It is just a fluid cyst." I might here say that the use of a hypodermic needle or simple puncture is a most misleading and useless procedure. There is, lastly, our teaching, which is grievously at fault in this matter, as it does not sufficiently lay stress on the necessity for an immediate and thorough investigation.

Let it be clearly stated at once that no one has any right to tell a patient that a lump which has no characteristic at all is nothing; no one can tell. But yet the procedure I have laid before you from one cause or another is that almost universally adopted in practice.

We know that malignant disease must start in a small area, and yet how many cases are operated upon before anyone of any experience can diagnose them! By the time they can be diagnosed with certainty they are no longer to be considered early cases: they have spread to such an extent that they are now characteristic of the disease. These should be classed as advanced cases in which it should clearly be understood the prognosis has become grave. We do stumble on early cases sometimes, it is true, but the gospel of immediate investigation has yet to be preached a long time before it will be generally accepted. It is rational, it is right, it is only fair to the patient, and it will be generally accepted some day. The other day I came across an old-fashioned physician who advised against an operation for well marked recurrent appendicitis because "the last attack was only a mild one." That advice is now the exception, but twenty years ago it was the rule. We are still in this old-fashioned stage with regard to diseases of the breast.

Now, what can we do in early cases? We may as well confess at once that by the ordinary methods of inspection, palpation, etc., we can get no farther—we cannot, in fact, make a diagnosis. We can only say that there are as yet no characteristic features of malignancy; but if we are not to sit down calmly and deliberately and wait for these features to develop under our noses we must do something more. The probabilities are, in sporting parlance, something between two and three to one that the mass is malignant; that alone should urge us forward.

What are the innocent masses, adenomata, cysts, chronic

mastitis from whatever causes, tubercle, lipoma, gumma, hydatid?—we need go no farther into the rarities. Which of these are important? Adenomata, which have a very typical and definite feel however small, occur in young subjects, and are nearly always removed at once when diagnosed; they offer very little trouble.

Deeply seated lipomata, gummata, and hydatids may be placed aside too, for all practical purposes, for they are rare and still more rarely diagnosed. Tubercle, also, unless it is advanced, or has ulcerated, is much more often diagnosed by the microscope than by any other means. There remains, therefore, that large group of cysts, and chronic mastitis, and involution masses. These arise in the same period of life as malignancy develops. In the early stages they have the same lack of characteristics as early carcinoma. They may cause more pain, but not always. Do what we will, the microscope is the only method of distinguishing between these classes.

I think it should be pointed out to every patient over 30, and certainly to everyone over 35, that the microscope is the only method we have at our disposal of arriving at a diagnosis without losing so much time as to render the outlook exceedingly grave if a growth should prove to be malignant.

Perhaps I should add here a note of warning about the danger of acquitting a tumour on no other grounds than that of the age of the patient. I know of two cases of cancer of the breast which occurred under 12 years of age, and many which occurred in the teens. Rodman collected 5,000 cases, of which nearly 10 per cent. were under 30 years of age. These facts alone will show you that you are acquitting a very doubtful tumour on very inadequate evidence.

How is the investigation to be carried out? We do not want to cause more disfigurement than is necessary. Luckily what is necessary can easily be done without leaving any visible scar. The operation is associated with the names of Dr. Thomas and Dr. Collins Warren of Boston. It consists in making a sweeping incision in the circumference of the breast below and to its outer side. The incision extends nearly half-way round the breast, and goes right down to the muscles. The breast is then lifted up so as to expose its deep surface. The deep surface even of the upper part of the breast can thus be brought into view. A wedge shaped portion of the breast is then removed, containing the suspicious mass in its centre. The wound can then be closed. Once free of the body the mass may be cut into and inspected. Often this gives most valuable information, though it should also be borne in mind that the knowledge thus gained may be misleading, as the cases quoted below prove only too well.

If one can arrange to have a pathologist with a freezing microtome waiting to cut a section this may be done, and the microscopical examination made there and then in the course of a few minutes. The surgeon can be told, with a fair amount of certainty, whether he has done all that is needed, or whether he should proceed to do the complete operation.

As a rule it is only in hospital that we have the advantage of a pathologist upon the spot, most of us being content to wait the verdict after a lapse of some days, and then if necessary perform a second operation. There are pros and cons for both ways, as I have known the freezing microtome give a wrong diagnosis, simply because in the hurry the wrong piece of tissue had been frozen and cut, or the section had not traversed the growth. To me the more methodical examination conducted in the laboratory seems the safer of the two, especially if the raw surface is seared with the cautery, or the lump cut out by this means so as to close the ends of the lymphatics.

It matters not which plan is adopted, so long as this method of diagnosis and treatment is urged on the patient, and it is explained to her that the responsibility for delay rests solely with herself, for her medical man can give her no further help in the matter. Delay is the method relied upon heretofore; it should now be discarded. Delay means spread and the development of characteristic signs, but at what a price! The needed information can be obtained with certainty within a few days by the operative means.

The following cases illustrate the method; many others might be quoted.

#### CASE I.

A lady, aged 50, seen in private, had noticed a small lump in her left breast for some two months. There was no pain. As the lump did not go away she had come for advice. Examination showed a small indefinite mass or ill-defined thickening, hardly a lump, deeply placed in the upper and outer quadrant of the breast. It was hardly perceptible to the flat hand as the patient was well

developed. There were no signs or symptoms of malignancy, and no glands to be felt. She was advised to have it investigated. It was removed by circumferential incision. To the naked eye it looked doubtful. It was sent to the pathologist, who returned a verdict of carcinoma. A complete operation was performed after the lapse of a week. There has been no sign of a recurrence since.

The following cases show that the method must be carried out systematically and carefully, and that no reliance whatsoever must be placed upon examination by the naked eye. This last truth I find personally is very difficult to learn. The difficulty of diagnosing the true nature of the mass by any other means than by microscopical examination is illustrated by Case II.

#### CASE II.

A lady, aged 54, under the care of Dr. Fiddes, was seen on November 8th, 1920. About a month previously she had noticed a small lump in her right breast which had caused a small amount of pain on stretching and reaching with her arm. There was nothing of importance in her family or previous history.

A very small but indefinite mass, deeply placed, about the size of a date, was detected just outside the nipple. The skin was free but the mass was incorporated in the breast. There was no discharge from the nipple. The nipple was attached to the mass and appeared slightly retracted; this, however, she denied, and said that the nipple had always been like that. There was one small gland in the axilla. The diagnosis lay between a cyst and early scirrhus.

The same procedure above advocated was advised, and in November the mass was removed. It seemed quite obvious to the naked eye that it was a simple mastitis, but it was sent to the pathologist. In the meanwhile the friends were told that it was probably quite simple and were reassured. A few days later the pathologist reported that the mass was a carcinoma of the ordinary scirrhus type. The patient had to be told, and a radical operation was performed. There has been no sign of a recurrence.

However awkward it may be to tell the patient disagreeable truth, after having assured her that the mass was to all intents and purposes a simple condition, the gain in having got the condition so early amply compensates for the unpleasantness. It, however, illustrates how unreliable is an examination by the naked eye.

#### CASE III.

A single woman of 45 was sent by Dr. Kellett to see me in 1911, with what was obviously a chronic interstitial mastitis of the involution type and cystic in character. There was such pain that she wished to have the mass removed. The whole breast was removed by the circumferential incision, the nipple being left. It was a mass of involution cysts and mastitis. A portion was sent to the pathologist; this portion, however, was innocent. I did not see her until 1912, when she said that seven months previously she had noticed a tiny nodule in the region of the scar, and later others came, but she took no notice of them as they were some distance from the scar. She had only gone to her doctor again the night before. Her condition now was as follows: There was a ring of small nodules varying from the size of a wheat grain to that of a pea, about nine in number, all situated about two and a half to three inches from the nipple, mostly to the upper and outer side of the breast. They were obviously secondary growths. A complete operation was then performed and a large area of skin had of course to be removed, the deficiency being made up by sliding in skin from the back. The pathological examination showed them to be carcinomata, and as the whole breast had been removed they were obviously secondary to a primary focus in the removed breast. The patient was seen this year with no signs of recurrence.

In this instance a small part only of what had been removed was sent to the pathologist, and this portion did not contain any malignant tissue.

This was one of my earlier cases, and since that time I have always been careful to send to the pathologist the whole mass as it has been removed.

The last case I wish to quote illustrates how one may be misled by naked-eye appearances in just the opposite direction and mistake a simple tumour for a malignant one.

#### CASE IV.

A Russian lady, aged 42, seen in private last year, said she had noticed a small lump in her left breast for twenty years, but it had now started to grow larger; she thought there was one coming in the right breast.

There was an ill-defined mass in the left breast in the upper and outer quadrant. There was no pain. It could be felt with the flat hand, though the breasts were large. The skin was distinctly attached to the mass, but the nipple seemed free. In the right breast was a similar but smaller mass just above the nipple, and here again the skin was drawn down and did not move so freely. There were glands in both axillae. On account of the history that she had had the lump in the left breast for twenty years a diagnosis of old mastitis was made, but at the same time she was urged to have the mass removed. She consented.

At the operation the breast was turned up and a portion radiating from the nipple was removed. On cutting this open a small area a little larger than an almond, but with an irregular outline, was found surrounded by mastitis. This area was grey and presented

every appearance of being malignant. It cut like an unripe pear; it retracted and hollowed on section: on scraping with the knife it gave the well known "cry of a cancer." Cancer I thought it to be, and proceeded to do a radical operation.

The mass was sent to the pathologist, and the husband was told what we had found, what we feared, and what had been done. He was also informed that the other breast would have to be treated in the same way.

There was a delay in receiving the report from the pathologist, but as the case was so obvious one did not give the matter a second thought. What was my surprise, therefore, the evening before the second operation had been arranged for, to get word from the pathologist that the mass was an old fibro-adenoma. The news was at once communicated to the patient and her friends. The next day a circumferential incision was made and the growth removed from the remaining breast. On cutting this across, exactly the same typical carcinomatous appearance presented itself. An experienced surgeon of high standing who was present gave it as his opinion that the mass was undoubtedly carcinoma, although I had purposely told him my previous mistake. We were now in a quandary; there was this tissue in my hand presenting to the eye every known appearance of carcinoma. Should we perform a radical operation or be content with the partial one, relying on the experience we had gained from the other breast? Would we get the same verdict from the pathologist as in the other breast? We had promised the patient that we were only going to do quite a partial operation. Should we have to come later and inform her that the pathologist's report required us to do a larger one? It was a very difficult position. I decided to close my eyes to the naked-eye appearances, to shut my ears to the surgical advice of our friend, and be content with a partial operation.

Fortunately, the pathologist returned again the same verdict as in the case of the other breast—that it was an old fibro-adenoma.

These cases have been quoted to show that, though radical investigation must be urged on patients at an early stage, there are yet many pitfalls for the unwary, and the very greatest care is necessary to arrive at a correct diagnosis.

## MINOR TRAUMATIC DISABILITIES OF THE UPPER LIMB.\*

BY

P. JENNER VERRALL, F.R.C.S.,

BURGEON, MINISTRY OF PENSIONS HOSPITAL, SHEPHERD'S BUSH; CHIEF ASSISTANT, ORTHOPAEDIC DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL.

I HAVE used the word "minor" to exclude fractures, dislocations, and gross lesions of the vessels and nerves, but in a way it is a misnomer, as the disability caused by a fracture or a dislocation, though more complete at the time, is often more easily repaired, and as it is regarded by both patient and practitioner in a more serious light more care is taken in the after-treatment and re-education of the limb in order to ensure a perfect result. The greater disability caused by comparatively minor lesions of the upper limb as compared with similar lesions of the lower limb is, to my mind, explicable by the finer adjustment of the neuro-muscular mechanism and more sensitive connexion between brain and periphery found in the former. Unless we are professional dancers or something akin, we do not ask our legs to perform very intricate movements, and the sensation is not so acute. We are content if our legs will bear our weight and carry us along. Good evidence of this sensibility is seen in the behaviour of amputation stumps. It is quite rare to find in leg stumps what we call "pain of central origin," whereas an upper arm stump is frequently the seat of great pain, for which no local cause can be found, and on which no artificial limb has ever been worn. Bulbous nerve ends may have been excised again and again, even up to the plexus above the clavicle, and yet the pain continues. Even posterior root section often fails to relieve the pain, proving conclusively that the pain is of central origin, and a very long period must elapse before the cortical cells give up their hopeless struggle for activity. The only hope lies in active occupation of mind and body, thus diverting the nervous impulses into new channels and relieving the tension in the now useless mechanism.

I desire to call attention to the extreme importance of the presence of septic foci in other parts of the body in the conversion of a minor strain into an intractable disability. As common septic sources I would put in order of frequency the teeth (root absorption, abscess, and generalized pyorrhoëa), the tonsils (especially in younger subjects), the colon (chronic colon bacillus infection), the uterus or prostate, and the nasal sinuses. Unless these sources of infection are cleared up the

treatment of a minor lesion may prove wellnigh impossible. When these underlying causes have been excluded, the question of diagnosis turns on, first, the history of the injury—that is to say, the precise action that the patient was performing at the time symptoms first appeared; secondly, a diligent search for a spot tender on pressure; with these must be combined accurate knowledge of the structures underlying that spot; thirdly, the limb must be put systematically through its normal movements in order, noting by which of them pain is produced and whether or no pressure on the tender spot during the performance of these movements relieves the pain or not.

The vast majority of minor traumatic disabilities in the shoulder region are due to adhesions in or around the joint, the movements most frequently affected being those of abduction and external rotation. The shoulder is a simple joint, unstable in itself, and depending for its stability with the help of its own ligaments on the interaction of a complicated musculature surrounding it; its capsule is weak in all parts and actually lax beneath the joint at the apex of the axilla. Acute simple traumatic bursitis of the subdeltoid bursa is a condition described in the textbooks and frequently diagnosed, owing to the fact that tenderness is elicited below the end of the acromion process, but in my opinion it only rarely occurs. The source of trouble is much more frequently either strain of a muscular attachment or adhesions. With other more serious forms of subdeltoid bursitis we are of course familiar—such as tuberculous, gouty, or calcareous bursitis—and I would regard definite swelling in the situation of the subdeltoid bursa as an indication for taking a more serious view of the case, or at any rate for obtaining a skiagram of the shoulder.

As to adhesions, we must understand how these come about and how they can be diagnosed. We will assume that there is no clinical sign of a gross lesion and that the skiagram (if one has been taken) shows a normal joint. First we must exclude active arthritis, which may be present although the skiagram shows a normal joint. Pain and limitation of movement in all directions indicate arthritis. Sir Robert Jones expresses the matter well when he says that if there is limitation of movement in all directions there is probably arthritis; if even one movement is free there is probably none! The point is important, as the treatment of the two conditions is diametrically opposed—rest for active arthritis, movement for adhesions. Adhesions commonly give rise to pain and limitation of movement in one or more directions, but not in all, and come on fairly soon after the accident. Sir Robert Jones also calls attention to a condition which he terms "contusion of joint cartilage," such as may occur from a fall on the outstretched hand, pain and limitation of movement coming on gradually about a fortnight after the injury and being due to a process of repair in the damaged and bruised cartilage during which there is vascularization of the injured area. We have here the phenomena of an aseptic inflammation, and the treatment is determined by this. If due rest be given, the symptoms clear up, but if movement be allowed or forced at this stage, the recovering cartilage is further injured and recovery is delayed. However, the later history of such cases may well be that of "adhesions." As long as there are visual signs of active inflammation in the neighbourhood and of a definite arthritis, so long must we employ rest and soothing applications. When, however, this stage has passed we may allow movement without forcing it—that is to say, active movement, but not passive. Passive movement, apart from the full mobilization of a joint under an anaesthetic, is of very limited utility, and the temptation to employ it, although very great, should be firmly resisted. This applies to all joints. Assisted active movement should commonly take the place of true passive movement in the treatment of all joint lesions. If active movement is allowed and inflammation has passed, the movement of the joint should steadily increase in range. If it does not and the range begins to lessen, inflammation is still present and a further period of rest is indicated. If the range increases steadily with active use of the joint, let well alone. If it remains stationary, especially if the limitation of movement is in one or two directions only, the joint should be mobilized under an anaesthetic. It is commonly said that gas does not give sufficient muscular relaxation, but I maintain that with gas properly administered adequate relaxation can be obtained for the mobilization of all joints, with the possible exception of the hip. Under the anaesthetic all the normal movements of the joint should be carried through to the full extent,

\* Abridged from an address delivered to the annual meeting of the Essex Division of the British Medical Association July, 1922.

systematically and in order, and care should be taken to control both sides of the joint and to protect bones from fracture—by splinting if necessary. Active controlled exercises and massage should follow either on the same day or on the next day if much trauma to the joint has been produced by the operation. The correct principles of mobilization are not new, and are well recognized by orthopaedic surgeons, but are less well recognized by others, and failure to realize them permits patients to have recourse to less orthodox ways in order to obtain correct treatment. There is one more condition which, to the best of my knowledge, has not previously been described, but is not very rare. Owing to long continued strain of the arm in a person unaccustomed to great exertion, abduction of the shoulder becomes limited in extent when an attempt is made to perform it with the arm in the coronal plane. If, however, the arm is brought forward, a painful snap is felt (or even heard) over the front of the joint, and the arm can then be freely abducted. I have recently been investigating this condition, and ascribe it to a slipping to and fro of the short tendon of the biceps over the lesser tuberosity of the humerus and the subscapularis tendon, which immediately underlie it. I thought that possibly there might be a bursa in this situation, but I have examined some twenty subjects in the dissecting room and have found no trace of a bursa. I think the condition is purely mechanical, and the results of treatment confirm this view; ordinary treatment fails entirely to produce a cure, but if the elbow be flexed and the arm brought well forward by a sling so as to relax the biceps, and a pad be strapped in place over the short tendon of the biceps just exterior to the coracoid process, cure is certain in two to three weeks.

It is in the elbow that we find the commonest injuries. Golf, tennis, and cricket have each of them their characteristic strains. Flexors and pronators from the inner condyle, extensors and supinators from the outer, are liable to strain in turn, and it is the key to comprehension of these injuries to realize that excessive tension of a muscle is felt at its origin no less than at its insertion. The pathology of such injuries is usually as follows: a few fibres are torn off from their bony origin, the periosteum is raised, and there is haemorrhage both subperiosteally and into the interstices of the muscle fibres with all the ensuing phenomena of inflammation and fibrous tissue formation, possibly aggravated, as I have already mentioned, by the presence of some septic focus elsewhere in the body. In addition to these muscular lesions the elbow-joint or superior radio-ulnar joint may be the seat of traumatic arthritis, or of adhesions; the diagnosis and treatment are on the same lines as those already indicated for the shoulder.

The commonest muscle to be injured is the flexor carpi ulnaris. Although a flexor of the wrist the most important action of this muscle is a restraining one, preventing undue abduction of the hand, and it is commonly injured in returning forehand a hard drive at tennis or in removing a large and rocky divot from the ground at golf. Pain is felt over the inner condyle at the time, but the game can usually be finished, and it is not until evening that the arm stiffens—that is, to say, not until the haemorrhagic infiltration of the injured area is considerable. If immediate treatment be applied cure is usually rapid, but this is rarely possible, as we are not consulted soon enough. If opportunity occurs, a firm pad placed over the injured spot and strapped on will limit effusion and immobilize the muscle. The arm should be rested in a sling, if possible. Massage at this stage is unnecessary and may do harm.

The common tennis elbow is usually caused by a back-hand stroke. Its onset is similar to that of strain of the flexor carpi ulnaris, and pain is felt over the origins of the brachioradialis and radial extensors. The exact pathology of this lesion has long been in doubt. Probably in the majority of cases it is due, like other similar accidents, to muscle rupture, and can be treated as such; but in April, 1921, Osgood<sup>2</sup> of Boston described his own personal experience and gave a review of the literature, which is very instructive. After describing the mode of onset he notes the common symptoms of a sudden unexpected sensation of weakness and pain running down the forearm, leading the patient to drop objects; he notes also that the pain and the tenderness differ in severity with different positions of the forearm; but this is to be expected whatever the causation. The same applies to the slight swelling and increased feeling of elasticity, which he also mentions. X-ray appearances are negative, as was to be expected. He gives the various theories of etiology that

have been advanced: (1) tearing of muscular origins; (2) periosteal injury and periostitis; (3) post-influenzal periostitis; (4) injury to radio-humeral capsule; (5) arthritis of the radio-humeral joint. Unquestionably all of these occur and are responsible for the symptoms in certain cases; in my opinion the first two are those commonly to blame. He goes on to describe his own condition, which I have not seen, or at any rate have not verified, but which is well worthy of attention. He was treated in the usual way without permanent benefit. Dissection was made to see if a bursa were commonly present in this situation, and such a bursa was found beneath the conjoined tendon over the radio-humeral joint. An operation was performed on him under local anaesthesia, and an extremely sensitive area was found with outlines of a dirty grayish-white, but with no distinct sac. This was removed and found to be chronic inflammatory tissue. This operation cured him, and subsequent dissection showed the bursa present in seven consecutive elbows examined.

Dr. Osgood has performed a very useful service in calling attention to the presence of this bursa and its tendency to inflammation; but we frequently meet with inflamed bursae, and it is not always necessary to dissect them out. If we make use of appropriate non-operative methods, and pay attention to the possibility of septic foci elsewhere in the body, and remember, with thanks to Dr. Osgood, the possible existence of the bursa he describes, we may reserve excision of the inflamed area for extremely chronic and refractory cases in the same way as with cases of prepatellar bursitis which resisted treatment by other means.

In golf the pronator radii teres muscle comes into action to a degree not commonly realized, particularly in mashie and niblick shots out of bad ground, in the performance of which obviously forcible pronation causes the club to bite into the ground. I have never seen strain of this muscle of any great severity, but I can well imagine it occurring in a not over-muscular player.

In the treatment of cases which have had no early treatment or are refractory, but in which for the time at least there is no question of any operative measures, all septic foci must first be sought for and adequately treated until the toxic output has entirely ceased. Secondly, complete rest to the part must be obtained. The guide to correct treatment lies in an accurate knowledge of the functions of the injured muscle; the limb must be fixed in a position which relaxes the injured muscle while allowing as full play as possible to the uninjured ones. This is not always easy, but it is unsound treatment to limit the function of a limb more than can be avoided, as the muscles will require re-education and there is no method so good as a case or a plaster splint, which has the advantage that it is removable and therefore permits of massage. Where massage is unobtainable, or there is doubt that the patient will continue to wear the splint when not under the eye of the medical man, it is better to apply a plaster case for about six weeks, and rely on functional activity of the arm to restore use and power after its removal. By massage we seek to remove the effete products of inflammation and to loosen the limiting fibrous tissue that has formed. The affected area is moderately tender, though not as tender as it was when first injured. Massage to the required spot should be deep and vibratory and performed with the hand and not with a mechanical vibrator with an insensitive surface and of a force difficult to control. The pain produced should be little or absent, and the force of the pressure and vibrations should increase *pari passu* with the relief of the patient and the diminished sensation of resistance to the fingers. At the same time conservative centripetal massage should be given to the other muscles in order to keep up their tone and circulation, and controlled exercises given to these other muscles in such a manner as not to strain the injured part. This principle of relaxation applies to nearly all the minor injuries of which I am speaking; the essential point is to know exactly what position produces relaxation. The rest is easy.

In strains of the origin of the flexor carpi ulnaris the ulnar nerve is often thickened and tender and displaced or displaceable forwards even to the front of the internal condyle. Associated with this may be definite symptoms of ulnar neuritis, pain and tingling in the little and ring fingers, and so forth. The degree of mobility of the ulnar nerve in this region varies considerably under normal conditions. I have not been able quite to make up my mind whether these are cases of injury to an abnormally mobile nerve or whether the nerve is actually loosened by the injury, for abnormally

mobile nerves do not give rise to any symptoms. I am inclined to think that the injury loosens the nerve and also causes a traumatic neuritis; the nerve passes under a fibrous arch from which a certain number of the fibres of the flexor carpi ulnaris actually arise, and which may well be broken, thus liberating the nerve. This is a most painful condition, however it arises; it is treated initially by placing a soft wool pad behind the condyle and strapping it in place. In old-standing cases I have no hesitation in operating. The nerve is cut down on behind the condyle and either transplanted definitely to the front of the condyle and sutured into a bed made for it in the flexor muscles, or fixed back into its normal position by a strip of periosteum turned down from the humerus. Either of these proceedings will cure the condition, as the neuritis rapidly subsides when the nerve is no longer subject to recurrent injury.

The ligaments round the elbow, with the exception of the orbicular ligament, are of comparatively slight importance, and the trouble here is rarely ligamentous in origin. Similar muscle strains to those mentioned above occur in the insertions of the biceps, brachialis anticus, and triceps, and can be easily diagnosed by the situation of the tenderness and the pain on movement; they are readily treated on the same lines by relaxation of the damaged muscle. It is rarely necessary to suture the ruptured tendon. Bursitis of the bursa around the insertion of the biceps also occurs, but is not deserving of any special mention.

Partial or complete rupture of a muscle belly, such as the biceps, should be treated by complete relaxation of the muscle, and two pads strapped in position so as to approximate the divided ends and limit effusion. Union is always by fibrous tissue, and some degree of permanent impairment of function must always be anticipated, the degree depending on the extent of the injury. While massage may be employed as soon as the initial inflammation passes off, no movement of the muscle should be allowed until repair is complete. Suture of a muscle belly is, in my opinion, useless, as, the union being by fibrous tissue only, the muscle degenerates, and either a fresh rupture occurs or the fibrous tissue stretches when any great strain is put upon it. Where rupture has taken place, either through tendon or, more commonly, at the junction of tendon and muscle belly, open operation for repair by suture and careful after-treatment hold out good prospects of cure and should always be attempted.

In the neighbourhood of the wrist, where there are many tendons lubricated by a complicated system of tendon sheaths, teno-synovitis is naturally common. Perhaps the commonest site is along the tendons of the extensor communis digitorum. Simple teno-synovitis is caused by strain or excessive use of a tendon; the sheaths and parts around become inflamed and the lubrication defective. To treat such a condition by counter-irritation with iodine while permitting the full use of the tendons is like pouring water over an overheated car engine while allowing it to continue running with insufficient oil. This much used simple remedy will only cure the slightest cases, and is not really economical in time. If teno-synovitis of the extensor tendons be treated for a few days by complete rest of the fingers on a long cock-up splint and either counter-irritation or cooling lotions be applied, cure will really be more rapid; if the finger extensors alone are affected, it is not necessary to include the thumb, and thus the hand is not entirely disabled during treatment. Teno-synovitis thus treated will soon subside, but there is a special form which is particularly obstinate. It occurs in people—mainly women—who either play the piano very frequently or who have frequent need in their occupation to span the hand widely, as in the movement of playing an octave or grasping a large object in one hand. The symptoms are absolutely characteristic. There is a general sensation of weakness in the hand and pain and tenderness on pressure over the deep groove on the back of the radius, in which the tendon of the extensor longus pollicis runs, and along the tendons of the flexor and extensor carpi ulnaris. As may be readily noted on one's own hand, these two latter are synergic muscles in abduction of the thumb, preventing the abduction of the whole hand at the same time as the thumb. It may be worth mentioning that, as I wrote in the BRITISH MEDICAL JOURNAL some years ago, in such patients as these the deep groove of the extensor longus pollicis may be converted into a narrow canal by overgrowth of bone and thick fibrous tissue. To such an extent may this occur that I have twice been compelled to operate to free the tendon and flatten out the groove by chiselling away bone. The results of operation were absolutely successful, and it can quite easily be done

under a local anaesthetic. In the milder form of this condition, rest from piano playing and the avoidance of all actions which necessitate a wide grasp, such as holding a large vase, supplemented perhaps by wearing a wrist strap for a time, may suffice to cure, but I have found it necessary on some occasions to fix the wrist and hand in plaster with thumb abducted and hand deflected to the ulnar side for six weeks. This, being a much more drastic performance, has, in addition, a curative effect upon the functional element which is usually present in these cases, leading the patient to complain greatly of what cannot be a very severe pain.

To the prevalent custom of wearing a wrist-strap more or less permanently after a strain in the region of the wrist I have no objection, provided the patient be encouraged to dispense with the strap as much and as soon as possible, or at least to wear it only when engaged in some laborious work or sport. The strap gives a comfortable feeling of support, supplements the annular ligaments, and at the same time limits and controls the movements of the tendons as they pass through them, thus making a useful transition stage between absolute fixation and free movement. An elastic knee-cap, on the other hand, has a permanently constricting effect on the underlying vasti muscles, on which a large part of the lateral stability of the knee depends, and produces wasting and weakness of them, owing to inhibition of their blood supply and limitation of their activity. It is quite otherwise with the wrist, for the simple reason that in the wrist, with the exception of the pronator quadratus which lies deeply and the lower part of the flexor carpi ulnaris, there is no acting muscle to constrict and only a collection of practically avascular tendons.

Another disability that I would mention is mallet-finger, about which a series of letters appeared recently in the BRITISH MEDICAL JOURNAL; it is due to a rupture, partial or complete, of the extensor tendon on the dorsum of the last interphalangeal joint. It arises from a blow on the end of the finger, as in an ineffectual attempt to catch a cricket ball, and is often neglected in the early stages. The finger should be kept straight for three weeks on a straight palmar metal gutter splint. At the end of this time, if the rupture has been incomplete, the patient will be able to extend the joint voluntarily. If not, the tendon must have been completely torn, and an open operation for suture of the tendon, followed by splinting, is the only method that will suffice. In old-standing cases the structures on the flexor aspect may be so contracted that the finger cannot be straightened, and the question of amputation of the distal phalanx will arise.

Disabilities of the hand I propose to treat in a somewhat general manner, with more reference to general principles than to detail, as it is obviously impossible to cover every possible lesion. If we leave out such developed functions as piano playing, the functions of the hand may well be described as only two, grasping objects and picking up objects, and it is these two functions which we must endeavour to restore after injury. Apart from gross destruction of the hand or nerve injuries, the actual division of tendons and the after-results of cellulitis claim our chief attention. Owing probably to the greater complexity of their tendon sheaths, repair after suture is much less satisfactory in flexor than in extensor tendons, and although suture of cut finger flexors should always be carefully performed, when both flexor tendons of a finger are divided, a most guarded prognosis should always be given as to the subsequent utility of the finger; in manual labourers the hand is often more useful without the damaged finger than handicapped by a useless digit that impedes the action of its fellows. I do not, however, wish to be unduly pessimistic, as it is often possible to obtain a good result by careful after-treatment. Suture of extensor tendons is always promising, and even when there has been such a loss of tendon length that end-to-end suture is impossible, grafts of fascia lata are usually successful. I will say nothing of the immediate treatment of septic hands and fingers, except that acute inflammation is an indication for rest, and that too early movement should be avoided, as recovery of function is not hastened, but hindered thereby.

In order to be able to grasp an object satisfactorily flexion of at least two fingers is necessary, the possession of a thumb advisable but not essential, and a wrist capable of dorsiflexion essential if the grip is to be a strong one; for a good grip of a round object the preservation of the form and mobility of the transverse arches of the hand is of prime importance, and therefore the physiotherapy or, if necessary,

the operative interference with the metacarpal joints must not be neglected. The duo mobility of these transverse arches is also of importance in picking up objects, as without it, although opposition of the thumb may be free and unimpaired, the thumb cannot reach farther than the middle finger, and the fourth and fifth fingers cannot be used in conjunction with it. Abduction and opposition of the thumb are easily lost after septic wounds of the palm. If opposition is defective a band of adhesive strapping round the hand, keeping the thumb in opposition and preserving the palmar arches, reapplied as progress is made and the band loosens, is quite effective. For deficiency in abduction a series of small plaster splints moulded to the first interdigital space will gradually restore function.

Fingers may become stiff from a variety of causes, but assuming them to be potentially mobile and useful—that is to say, that all the structures essential to their mobility are present—their restoration to function is a purely mechanical problem. In dealing with the problem elsewhere<sup>1</sup> I described certain methods of treatment by metal splints and plaster that I had devised. I still use these methods and find them effective, but others have published other devices equally good, and the principles involved are in the main identical. If a masseuse move a stiff finger to and fro repeatedly, resistance is induced, often unnecessary pain, and a certain amount of reactionary inflammation. Should massage alone without mechanical aid be employed, the hand should have a preliminary bath treatment, preferably paraffin, and the massage immediately after should be confined to a single movement of the affected joint in each direction to the full extent possible without pain; the patient should then be encouraged and re-educated in active movements. I strongly disapprove of forcible mobilization of stiff fingers under an anaesthetic; though applicable to other joints, this method is not satisfactory for the fingers, and more gradual methods are indicated. The classification and the principles of treatment I advocate are as follows:

A. Fingers flexed when wrist is dorsiflexed, extension possible with wrist flexed. This, the type of ischaemic contraction due to shortening of flexor tendons, is best treated by Sir Robert Jones's method, the joints being straightened seriatim, beginning distally, leaving each joint in the deformed position until all the joints distal to it have been corrected, and retaining that correction by continued splinting, ending up with dorsiflexion of the wrist.

B. Wrist movement free, one or more fingers flexed at all three joints, contraction unaffected by position of wrist. One must aim at obtaining extension without losing flexion. I employ a metal splint extending beyond the fingers and terminating in a bar, fixed to the hand by plaster. To the affected fingers loops of adhesive plaster are fixed and tapes are tied between these and the bar. By gradual tightening of these tapes extension is obtained, but every day the tapes are released and the finger is brought back to its original flexed position and the tape then retied. There is then no loss of flexion; should this be noticed, extension is being carried out too rapidly and one must call a halt.

C. Free movement at the metacarpo-phalangeal joint, distal joints flexed. Gradual straightening on metal palmar gutter splints will suffice, flexion being preserved by daily movements, as before.

D. Metacarpo-phalangeal joints stiff in hyperextension, distal joints straight or slightly flexed. The important principle in treatment consists in getting the metacarpo-phalangeal joints to pass the dead point or straight line position. For this condition I use an ordinary short cock-up splint (which keeps the wrist dorsiflexed) with attached to it a quadrilateral wire loop springing from its palmar surface at the wrist and extending to the level of the metacarpal extremities. To this the fingers are flexed by tapes; daily movement as before.

These methods exert very great force, but can be graduated to a nicety; correction is gradual and gives no pain, and the range of movement is never lost. Tape traction is better than elastic, as there is no tendency on the part of the patient to resist it. Finally, employment of the hand, at first in gymnastic exercises and later in actual work, will put the finishing touches on the treatment.

## THE DOSAGE OF RADIUM.

BY

DAWSON TURNER, M.D. EDIN.,

IN CHARGE OF THE RADIUM TREATMENT AT EDINBURGH ROYAL INFIRMARY.

The duration of the application is a most important element in radium treatment, and it is one which there may be a tendency to overlook in institutions where large quantities of radium are available. Consider, for an example, a dose of 500 mg. hours, which would be a fair dose to administer to a small rodent ulcer. This dose might be given by 10 mg. of radium for fifty hours, or by 50 mg. for ten hours, or by 500 mg. for one hour. Does anyone contend that similar effects would be produced in each case? I have no hesitation in making the affirmation, based upon an experience of twenty years, that for each case there is a certain optimum combination of milligrams and of hours, and that this question is one for the radium expert to decide. Levin and Joseph,<sup>1</sup> from an experimental study of the influence of radiations on the development and growth of the crown gall on plants, have shown that the primary effect of radium or x-ray radiations consists in the inhibition of the proliferating power of the cancer cells and not in their direct destruction. The crown gall, tumour-like formation on plants is so called because the growth frequently appears where stem and root join (called the crown). It is due to a parasite and can be induced artificially by inoculating a plant with an agar culture of the micro-organism. Plants were inoculated by these observers and some were submitted to radiation and some kept as controls; the control plants developed large crown galls, the others none or stunted growths containing true tumour cells. Cancer cells go through a cycle of (1) youth, (2) maturity, (3) old age. At one time they are actively dividing and at another they are not, and it has been shown that they are more susceptible to radiations when their nuclei are dividing than when they are in any other stage. In certain stages they may be as immune as normal tissues.

The lesson to be learned from a consideration of these facts is that in order that the dose of radium may be effectual it must be applied for a certain time, for it is only by a prolonged application that we can make fairly sure of catching all the cancer cells in their susceptible stage. We may therefore conclude that small amounts of radium for prolonged periods are more likely to prove beneficial than large amounts for short periods. The oven may be too hot and the bread will be burned on the outside instead of being baked throughout.

To take another point: suppose one possesses 100 mg. of radium, in what quantities is it best to put it up into tubes? The answer depends mainly upon the nature of the diseased condition to be attacked, upon its situation, its area, its volume, and upon whether the radium is to be applied externally or buried in the growth. Take the case of a lymphosarcoma—perhaps the most susceptible of all growths to radium—of the size of a large orange; in this case it would be best to have the radium put up in 5 or 10 mg. portions in separate tubes, so that they could be distributed throughout the mass, and particularly arranged like sentinels around the borders of the growth, for in this way the central parts will be receiving cross-fire radiation from all the tubes, but the peripheral parts will only get efficient radiation from the peripherally placed tube which happens to be nearest. In order that the whole of a growth may be efficiently and uniformly radiated the radium should theoretically be uniformly distributed throughout it—in fact, the desideratum would be to scatter radium like pepper from a pepper pot throughout the mass. Though this is for several reasons impracticable yet the more nearly we can approach to it the better. Dr. Stevenson's needles are a means to this end. Small tubes are filled with the radium emanation and are enclosed in hypodermic needles for embedding in the neoplasm. There is a disadvantage which applies to all cases in which the emanation is used, owing to its steady loss of strength—namely, that the dosage is not known unless the tubes have been tested for their emanation strength before being employed and unless a table of their rate of decay be consulted. As the time element in radium treatment, as I have endeavoured to show, is important, emanation tubes have the disadvantage that they would have to be replaced from time to time by freshly charged ones. Where the application is external this would be easily done, but in

the case of a tumour, in which the radium is embedded, it would mean a minor surgical operation each time the emanation tubes were changed.

Another point of importance is to give the whole maximum dose at first, and not to break it up into smaller ones which are repeated. The latter course may in certain cases turn out a fatal error, and this chiefly because the malignant cells, which were stunned but not killed by the first application, will, when they recover, tend to breed cells which are more immune to radiation, until, the same process continuing after several exposures, only those cells will survive which are refractory to the rays. There is a tendency by natural

selection to breed cells which are immune, and further exposures will now only do harm. The knock-out blow should be given by a sufficiently long exposure to a sufficient amount of radium while the cancer cells are not suspecting an attack; they must be taken by surprise, so that they will be unable to organize a resistance and be incapable of putting up a serious defence.

Were more attention paid to these points there would, I venture to think, be fewer failures following radium treatment.

## THE FUNCTION OF THE ADRENAL GLANDS AND ITS RELATION TO CONCENTRATION OF HYDROGEN IONS.\*

BY

ROBERT McCARRISON, M.D., F.R.C.P.,

LIEUTENANT-COLONEL, INDIAN MEDICAL SERVICE; IN CHARGE OF THE DEFICIENCY DISEASES INQUIRY, INDIAN RESEARCH FUND ASSOCIATION.

(From the Pasteur Institute of Southern India, Coonoor.)

The object of this research was to inquire further into the causation of the adrenal hypertrophy occurring in inanition and in avitaminosis.<sup>1</sup> This hypertrophy is accompanied by an increased epinephrin content of the glands,<sup>2</sup> and is due, in the avitaminosis of birds, to the absence of vitamins A and B from the food. It is associated also, as shown by Cramer,<sup>3</sup> with an almost complete disappearance of lipoids from the adrenal cortex. The enlargement rapidly reverts to a more normal state when the missing vitamins are supplied. The question as to why hypertrophy of the adrenal glands should occur under conditions that give rise to greater or lesser degrees of atrophy of all other organs (the pituitary body in males excepted)<sup>4</sup> is of fundamental importance both in relation to the disorders of nutrition in which it is found and to the function of the adrenal bodies themselves. The facts suggest some purpose underlying their enlargement; some purpose, also, in their increased content of epinephrin. It was thought that it might be related to the increased concentration of hydrogen ions that occurs in avitaminosis. Recently Kato,<sup>5</sup> Takahira,<sup>6</sup> and others have drawn attention to the increased hydrogen ion concentration of nerves, spinal cord, heart, and blood vessels in polyneuritis avium. I have confirmed this observation in so far as it relates to the heart, and found also an increase of P<sub>H</sub> concentration in pectoral muscle. In a few cases of polyneuritis columbarum accompanied with effusion into the pericardial sac or with oedema of the tissues, the dropsical fluid has been well on the acid side of neutrality—pericardial effusion, for example, having a P<sub>H</sub> of approximately 6.5.

FIG. 1.—Showing the effect on the action of adrenaline hydrochloride on the iris of the enucleated eye of adding increasing quantities of N/10 HCl to Ringer's solution containing 0.02 c.c. of the commercial solution of adrenaline (1 in 1,000). As the P<sub>H</sub> of the medium falls, from alkalinity to acidity, the curve of pupils (sl) gradually heightens, and the range of action of the irides increases (shown as vertical continued lines falling from the points of maximum dilatation to points of maximum contraction). The curve of maximum dilatation and the ranges of action of the irides of control eyes subjected to the influence of the adrenal

adrenal of in are: approx. the tubes to which HCl was added are shown at the top of the figure. Initial P<sub>H</sub> of control tubes was approximately 8. It will be noted that under the influence of the metabolic activities of the eye the P<sub>H</sub> falls towards neutrality during the course of the experiment (thirty minutes).

Experiments were accordingly undertaken to ascertain the effect of changes in concentration of hydrogen ions on the action of commercial adrenaline hydrochloride and of the active principle of the adrenal medulla—epinephrin—in various media.

Enucleated eyes of the toad (*Bufo melanostictus*) were employed for the purpose; in all 1,300 were used. Each test on one eye was controlled by the other eye of the same animal. It has been stated that while adrenaline causes mydriasis of the enucleated frog's eye, it does not do so in the enucleated toad's eye. So far as *Bufo melanostictus* is concerned this is not the case. It has long been known that, by its action in stimulating the dilator mechanism of the iris, adrenaline causes mydriasis; but, so far as I can find, no reference is made in the literature to its further and, as I believe, more important action of sensitizing the enucleated eye in such a way that the iris responds more readily to the normal stimulus of light through its maximum range of action. This sensitivity of the toad's iris to the stimulus of light, when under the influence of adrenaline hydrochloride or of epinephrin, was utilized as a means of determining the effect upon the action of these substances of changes in concentration of hydrogen ions in various media. P<sub>H</sub> indicator tablets ("A. and H.") were used throughout; the P<sub>H</sub> values are therefore approximate.

The observations made in the course of the inquiry are enumerated below; the reader is referred to the full paper for details regarding them.

1. There is in the eye of *Bufo melanostictus* a peripheral mechanism which can act independently of the nerve centres. It is responsive to the stimulus of light within a limited range—25 per cent. dilatation in the dark to slit-like contraction on exposure to light—provided the eye be preserved in media of suitable composition and suitable P<sub>H</sub> concentration. In such it retains a gradually waning sensitivity for a comparatively short period—approximately two hours.

2. This mechanism can be so sensitized by adrenaline hydrochloride or by epinephrin that, under appropriate conditions, the iris will respond with enhanced sensitiveness to the stimulus of light through its maximum range of action. It retains its enhanced sensitivity for prolonged periods—three to eight hours—and in exceptional cases for even longer periods. This effect of adrenaline and of epinephrin is spoken of as the "adrenaline-iris-light-sensitivity reaction."

FIG. 2.—Showing the effect on the action of adrenaline hydrochloride of adding increasing quantities of N/10 HCl to normal saline solution containing 0.02 c.c. of the commercial solution of adrenaline (1 in 1,000). As the acidity increases the curve of maximum dilatation and the range of action of the irides drop precipitately until the critical point of acidity is reached at 0.03 c.c. N/10 HCl. The lesser degrees of acidity (0.01 and 0.02 N/10 HCl) enhance the action of adrenaline on the pupil of the enucleated eye; greater degrees (0.03 to 0.5 N/10 HCl) inhibit its action; greater degrees still enhance it again, while the irides tend to be fixed in the position of mydriasis. The bulk of inhibition is wider in normal saline than in serum

of control. It will be seen that the P<sub>H</sub> in the acid tubes rises towards neutrality. Experimental eyes, uninterrupted lines; controls, without acid, dotted lines. Duration of observation, thirty minutes.

\* Abstract of Twelfth Report to the Indian Research Fund Association on the Pathogenesis of Deficiency Disease. The full paper will appear in an early number of the *Indian Journal of Medical Research*.

It is markedly influenced by temperature conditions—heat inhibiting it, cold enhancing it.

3. The action of adrenaline hydrochloride and of epinephrin is dependent in some measure on the composition of the media in which the eye is contained: it is greatest in fresh serum and normal saline solution, least in Ringer's solution. Compare "controls" in Figs. 1, 2, 3, 5, and 6.

4. The action of adrenaline hydrochloride and of epinephrin is intimately correlated with the concentration of hydrogen ions in the medium containing the eye:

(a) Slight increases in acidity enhance the action of small doses of adrenaline hydrochloride or of epinephrin; greater increases of acidity retard it; greater increases still tend to fix the pupil in the mydriatic position. (Figs. 2 and 3.)

(b) As the medium approaches neutrality from alkalinity

the range of action of the irides, under the influence of adrenaline hydrochloride or of epinephrin, increases until at the neutral point they respond to the stimulus of light through a wide range of action. (Fig. 1.)

(c) As the medium departs from neutrality towards acidity the range of action of the irides, under the influence of adrenaline hydrochloride or of epinephrin, diminishes until a point is reached—"the critical point of acidity"—at which their action is completely inhibited. (Figs. 2, 3, and 5.)

(d) This point is attained when 0.03 to 0.04 c.cm. N/10 HCl is added to 10 c.cm. of serum containing 0.02 c.cm. commercial adrenaline solution (1 in 1,000) or 25 mg. of emulsion of guinea-pig's adrenals (equivalent to approximately 0.013 mg. of epinephrin). (Figs. 3 and 5.)

(e) Epinephrin, in appropriate dosage in normal saline and Ringer's solution, exerts its optimum effect within a range of P<sub>H</sub> of approximately 7.4 to 6.8; above or below these limits its action is inhibited.

5. By increasing the concentration of adrenaline hydrochloride or of epinephrin in proportion to the increase in acidity the gulf of inhibition can be bridged. (Figs. 3 and 4.)

In order, for example, that the same effect may be produced by adrenaline hydrochloride in 10 c.cm. of sheep's serum, containing 0.04 c.cm. N/10 HCl, as is produced in 10 c.cm. neutral serum three times the amount of adrenaline is required. (Fig. 4.)

6. The influence exerted on the action of epinephrin and of adrenaline by increased concentration of hydrogen ions is dependent on the quantity of epinephrin or of adrenaline hydrochloride present in the medium; while lesser degrees of acidity enhance the effect of the smallest dose of these substances that exerts any action whatever upon the eye, the

effect of larger doses may be retarded by the same degrees of acidity. (Figs. 5 and 6.) The maintenance of maximal functional activity by the iris of the enucleated toad's eye demands accurate adjustment between the quantity of epinephrin and the concentration of hydrogen ions.

7. The cortex of the adrenal glands, when associated in its action with adrenaline hydrochloride or with epinephrin, possesses the property of aiding the eye to bring the medium in which it is contained towards neutrality. This property may be lost by, or be greatly reduced in, the adrenal glands of birds suffering from polyneuritis columbarum. Its loss may possibly be correlated with the loss of cortical lipoids in this condition, and with the loss of lipoids from the blood in human beri-beri. Not only, therefore, is the adrenal medulla intimately related in its function to the concentration of hydrogen ions in the medium through which it acts, but the adrenal gland as a whole contributes its share to the regulation of the neutrality of the medium.

FIG. 4.

Fig. 3.—Showing the effect of adding increasing amounts of N/10 HCl to 10 c.cm. serum on the action of 0.02 c.cm. adrenaline hydrochloride solution (1 in 1,000). The lesser increases of acidity enhance its action, greater increases of acidity retard it; greater increases still again enhance its action. The critical point of acidity is seen at 0.03 to 0.04 c.cm. N/10 HCl, where the gulf in the curve of maximum dilatation is bridged. Experimental eyes, uninterrupted lines; controls, without acid, dotted lines. Duration of observation, thirty minutes.

Fig. 4.—Showing how the gulf of inhibition can be bridged by increasing the concentration of adrenaline in proportion to the increase in acidity of the medium. The "bridge" is shown as a dark line in the course of the dotted curve of dilatation taken from Fig. 3. Experimental eyes, uninterrupted lines; controls, without acid, dotted lines. Duration of observation, thirty minutes.

Figs. 5 and 6.—Showing (a) The effect of the lesser degrees of acidity—0.01 and 0.02 N/10 HCl in 10 c.cm. sheep's serum—in enhancing the action of approximately 0.013 mg. of epinephrin (from guinea-pig) on the irides of enucleated toad's eyes (Fig. 5). Effects on experimental eyes shown in uninterrupted lines; on control eyes, without acid, in dotted lines. (b) The effect of the same degrees of acidity in retarding the action of a larger dose of epinephrin—approximately 0.017 mg. (Fig. 6). In Fig. 5 the critical point of acidity is shown at 0.03 c.cm. N/10 HCl. Duration of observation, thirty minutes.

8. The serum of birds suffering from polyneuritis columbarum enhances the action on the enucleated toad's eye of minute doses of adrenaline hydrochloride; this action, interpreted in the light of the above results, indicates increased acidity of their serums.

9. The pericardial effusion from birds suffering from polyneuritis columbarum (P<sub>H</sub> approximately 6.5) retards the action on the enucleated toad's eye of minute doses of epinephrin (healthy pigeon's adrenal emulsion); this action, interpreted in the light of the above results, indicates that such effusions have reached "the critical point of acidity" at which the action of epinephrin is inhibited.

#### Conclusions.

1. The active principle of the adrenal medulla maintains and enhances the sensitivity of, rather than stimulates, the myoneural junctions of the true sympathetic terminals of the enucleated toad's eye, so that their response to the stimulus of light is more sensitive and their sensitivity is longer retained.

2. If this sensitivity is to be sustained and optimum function of the iris is to be maintained in media on the acid side of neutrality, the concentration of epinephrin must be proportionate to the concentration of hydrogen ions in the medium.

3. The observations recorded in this paper provide evidence that: (a) The enlargement—with increased epinephrin content—of the adrenal glands in inanition and in avitaminosis may be correlated with the condition of acidosis associated with these states. Its occurrence, for the most part, during the terminal phases of avitaminosis, its association with marked respiratory disturbances,<sup>1</sup> with oxygen-want,<sup>2</sup> with falling body temperature,<sup>3</sup> and with interference with oxygenation, and its rapid disappearance on the provision of the missing vitamins, suggest that it is an emergency effort on the part of the adrenal glands. (b) The attempted exercise of an emergency function by the adrenal glands may be expected to occur in all conditions of alkalosis or of acidosis.

\* As adrenaline hydrochloride rapidly deteriorates in India on exposure to air this concentration of adrenaline will probably be found too high where fresher stocks of the drug are available. All my observations were made with stocks that had been in India for several years. It is to be emphasized that the effects of hydrogen ion concentration on the action of adrenaline or of epinephrin are demonstrable with such minimal amounts of these substances as exert any action whatever upon the enucleated eye.—R. McC.

## EMBOLISM OF THE RIGHT BRACHIAL ARTERY AS A COMPLICATION OF LOBAR PNEUMONIA.

BY

A. H. D. SMITH, M.C., M.B., Ch.B.,  
LLANELLY.

The rarity of embolism of a main arterial trunk as a complication of lobar pneumonia, and the unusual bacteriological findings on examination of the blood, prompt me to make a record of this case.

W. J., aged 39, an insured person who worked as a labourer in a tinplate works, on October 16th, 1922, felt chilly and had a rigor after having been exposed to cold and getting wet through during a drinking bout. On October 17th I found him complaining of pain in the right side of the chest. The temperature was 104°, pulse 110, and the sputum was rusty. The right upper lobe was found to be the site of lobar pneumonia. All over the rest of the chest were signs of chronic bronchitis. Crisis occurred on the ninth day; at no time was there any real cause for anxiety, and apart from a soft systolic bruit at the apex there were no physical signs or symptoms of any cardiac affection. After the crisis convalescence was uneventful until the fourth day, when he began coughing badly, expectoration was profuse, the temperature was elevated, and sweating was marked. There were signs of bronchitis over both lungs; over the pneumonic area in the right lung the breath sounds were cavernous, and there were abundant crepitations. Night sweating was profuse and occasionally delirium was marked. Tubercle bacilli were not found in the sputum, but the clinical picture and the facts which came to light in the family and personal history strongly supported the view that the patient was now suffering from an acute tuberculous infection of the right lung. I was informed that the patient had, after his discharge from the army, been under treatment at a military hospital for tuberculous disease of the spine. His only brother had died recently of tuberculous infection of the lungs. Examination of the heart during this period showed no abnormality save for the soft systolic bruit at the apex previously noticed.

This was the clinical picture up to November 9th. On November 10th, during my visit in the morning, the patient told me that during the night he had been seized with very acute pain in the right arm; examination of that arm, conducted with difficulty owing to the great pain caused by the slightest movement, showed no apparent difference from the other; the heat in both was equal; there was no swelling in the right arm and no difference in colour between it and the sound arm. There was, however, exquisite pain in the affected arm and paresis of the muscles. The hyperaesthesia was confined to the area from the wrist to the shoulder. There was almost complete anaesthesia in the tips of the thumb and fingers. The right radial pulse was absent both to the finger and to the stethoscope. Following the course of the radial upward no pulsation could be felt in the ante-cubital fossa. At the level of the posterior wall of the axilla, in the line of the vessel, a very tender lump about the size of a small hazel nut could be felt. The surrounding structures appeared normal. Above this level the vessel could be felt pulsating strongly. The radial pulse in the left side was present and bounding in type. An examination of the heart revealed nothing further than the soft systolic bruit already noted. I felt I was dealing with an embolism of the right brachial artery, and thought that the probable source was an infective endocarditis. The cardiac physical signs at this stage were, however, not in any way pronounced.

The right arm was wrapped in cotton-wool and immobilized. For the next three days treatment was expectant, and a careful examination of the arm and heart was made daily. The appearance of the arm never changed. Compared with the sound arm there was no difference in size, heat, or colour. The hyperaesthesia, however, remained marked, as did the anaesthesia of the tips of the thumb and fingers. The patient was profoundly intoxicated, delirium became marked, and night sweats became very heavy. The cough was less, but the physical signs in the lung were still those of acute phthisis. On November 11th and 12th there was no alteration in the physical signs in the heart. On the latter day he was seen with me by Dr. Samuel Williams, who agreed that the diagnosis was probably septic endocarditis following lobar pneumonia, and that the embolus was a result of the endocarditis. On that day definite signs of endocarditis were present in the shape of marked systolic and presystolic bruits at the apex. The murmurs were harsh and ran into each other. At the base of the heart a soft, high-pitched systolic bruit could be heard distinct in pitch from the murmur present at the apex.

On November 13th a blood culture was made and sent by hand to Dr. Sladden, pathologist, Beck Laboratory, Swansea General Hospital. At this time the physical signs were as on the previous day. The general condition of the patient was very poor indeed, and he might be described as being in a typhoid state with the low type of delirium. I was called hurriedly to see him about 10.30 that night. On my arrival a few minutes later I found he was dead. A few minutes prior to my arrival he had been talking quite sensibly to his friends. They said he seemed to fall off to sleep and then they found he was dead. I was unfortunately unable to get permission to perform a post-mortem examination.

I have recorded the case because embolism of a main arterial trunk as a post-pneumonic complication is unusual. Osler<sup>1</sup> records a case of embolism of the femoral artery as a

pneumonic complication and states that it is very rare. In his case the complication occurred during the height of the fever, and the limb had to be amputated. The patient recovered.

In the case here recorded the obstruction was evidently complete and sudden. At no time was there any sign of interference with the circulation such as might necessitate surgical interference. Apart from the paresis and the nerve symptoms the limb was apparently normal. The obstruction must have been below the circumflex artery, and the condition of the arm again demonstrates the wonderful collateral circulation which exists in the upper limb. Complete obstruction of a main trunk with so little interference must, I think, be a very rare condition. Other points of interest in the case are:

1. The absence of definite signs of endocarditis in the early stage of the embolus.

2. The difficulties of diagnosis owing to the clinical picture in the lungs, so suggestive of acute phthisis.

3. The result of the bacteriological findings of the blood. Dr. Sladden's report was as follows:

"A plentiful growth of streptococcal chains occurred. Fuller tests showed this to be a non-haemolytic strain with the sugar reactions of *Streptococcus salivarius*. It was not bile-soluble, and grew readily on ordinary broth medium. It was therefore not in any way related to pneumococcus as usually identified."

I had expected the blood culture to reveal the presence of pneumococcus. Were the endocarditis and embolus the result of pneumonia or were they independent of the primary condition? Unfortunately the sputum was not examined for the streptococcus which was found in the blood.

## THE BLOOD AS GUIDE TO EARLY DIAGNOSIS IN LEAD POISONING.

BY

ROBERT CRAIK, M.D. GLASG.,

EALING.

LEAD poisoning is commoner than is generally supposed, and it is useful for practical purposes to recognize four classes of cases. The industrial includes workers engaged in smelting or making white lead, etc. This class is invariably detected by experienced medical men at the works. In general practice cases are mainly occupational—painter, plumber, etc. Recently there have been more cases than usual in painters. The practice of moistening the sandpaper with oil is practically unknown in London, and it is fine dust arising from dry sandpapering indoors which does the damage. I have known a healthy man to contract acute plumbism in this way in three weeks. Painters often drink much beer, and in such cases constipation is not to be expected with the colic.

Criminal cases used to be frequent in the Midlands, but I have seen only one in London. Diachylon is taken to produce abortion early in pregnancy by women—generally married women. Symptoms are often vague or misleading: constipation, vomiting, even albuminuria and headache, may be attributed to the condition, and abdominal pain that would otherwise secure attention is minimized by the woman as she hopes it is the prelude to miscarriage. The gums may give no help as the patient may have artificial teeth. Further, slight pyrexia is not unusual and agonizing colic may be attended with urgent vomiting—not unlike that due to an acute abdominal lesion. Only early diagnosis can save these women from serious illness, and in no class is blood examination so helpful.

All other cases may be lumped together as domestic and arising from food, drink, etc. Recently there has been an outbreak in this district due to accidental contamination of beer. But of 9 cases seen since midsummer only 3 were due to beer alone, though in 3 others it was probably an important factor. In the remaining 3 beer could be excluded—in one the source remains unknown, but in two painters it was occupational. These two were severe and conspicuous examples of acute lead colic.

In 30 cases of all kinds I have seen wrist-drop only once, and the patient (potman) developed encephalopathy about a year later and died. Another case (criminal) developed the encephalopathic type, but recovered after a long illness. In 28 there was practically no obvious symptom after a

fortnight's treatment. The longer diagnosis is deferred the greater are the variety and the duration of the symptoms. To hesitate in the absence of wrist-drop is like waiting for locomotor ataxia before diagnosing syphilis. In 19 out of 20 cases the patient first seeks advice for abdominal pain, which may be severe colic or only vague discomfort, and it is only in occupational cases that lead is likely to be suspected. In the latter a blue line is seldom absent, but this is not conclusive evidence.

1. *Blue Line*.—In industrial cases this is practically always present, but it may also be found in healthy workers. It means deposit of lead on the gums and is acquired from dust. In occupational cases the line is of more importance and means faulty habits, which are sure to end in plumbism if they have not already done so. In domestic cases where lead has been ingested in minute quantities in beverages, even when symptoms of poisoning are present, this sign may be absent. It is generally rather faint, and I have known such a case still undetected a fortnight after admission as alcoholic neuritis to the ward of a teaching hospital. Blue line demands careful examination of the patient or worker, but diagnosis must always be independent of blue line, which remains only valuable presumptive evidence. All are agreed as to the importance of early diagnosis in syphilis, and this is not less essential in plumbism. In order to effect this, diagnosis must depend mainly on a clear conception of the importance of two factors—lead in the urine and punctate basophilia in the blood film.

2. *Lead in the Urine*.—We are assured that lead may be found in the urine of healthy industrialists. In them minute quantities are always present in the system, but satisfactory elimination by kidneys and bowel is said to prevent accumulation and poisoning. This can hardly be regarded as satisfactory, and in my opinion such cases require further investigation. In lead poisoning the metal is always present in the urine and remains for weeks or months after treatment is undertaken. In the case of suspicious symptoms examination of the urine affords valuable diagnostic evidence, or, alternatively, altogether excludes lead. It should be oftener employed.

3. *Punctate Basophilia*.—This sign is neglected because its significance is misunderstood. It is necessary to recall a few facts of haematology. Polychromasia is a sign of unusually active erythropoiesis, and is conspicuous in the blood of the newborn babe, where it is associated with nucleated reds. In adults polychrome erythrocytes are still readily attracted into the blood stream, and appear in minor anaemias of convalescents and even after moderate haemorrhage, whereas erythroblasts only appear in more serious anaemias or after severe haemorrhage. In the so-called pernicious anaemias a toxin is also exciting the marrow to pathological regeneration. The first indication of this is the appearance of punctated erythrocytes, which later on are associated with megaloblasts, giving a blood picture of anisocytosis, polychromasia, and normoblasts (normal regeneration), combined with poikilocytosis, punctate basophilia, Cabot rings, and megaloblasts (pathological regeneration). All these may appear fairly early in mild lead intoxication, but for some weeks there is usually only anisocytosis, polychromasia, and punctate basophilia. Thus lead acts directly on the marrow in a similar way to the toxin in a pernicious anaemia. In malaria at every paroxysm the marrow is excited in the same way, but the reaction is transient. With these exceptions, pathological regeneration is seldom seen, and it is safe to say that, in the absence of serious anaemia, punctate basophilia is more likely to be caused by lead than by anything else. Now, anaemia is never serious in the early weeks of lead poisoning. Basophilia is pathological, and demands investigation just as much as albuminuria or glycosuria. So long as it is present something is acting injuriously on the marrow, and if this is lead the urine will contain a trace of the metal even in the absence of corroborative symptoms.

As I have indicated, basophilia is only one in a series of biological reactions inevitably excited by small doses of lead. When diagnosis is early—whatever the treatment—the reaction usually disappears within three months, and it is interesting to watch the subsidence of the reaction in the blood film. Not much difference is seen for a month, but soon afterwards blasts disappear in mild cases and search for basophils becomes necessary, though these can usually be found for two months. With the help of the Clinical Research Association I have compared this with disappearance of lead from the urine. In a mild case due to beer basophilia was still seen fifty-two days after ingestion ceased, and half a pint

of morning urine gave a trace of lead. In a more severe case of painters' colic erythroblasts were found thirty-nine days after leaving work, but a chance sample of eight ounces of urine gave no result. On the fiftieth day there were easily found anisocytosis, polychromasia, and punctate basophilia, and, after a search, Cabot rings and one punctated erythroblast. The whole twenty-four hours' urine was collected for the same day and gave a trace of lead. Apparently these two signs disappear about the same time.

I have already pointed out how basophilia may be used to exclude lead poisoning (BRITISH MEDICAL JOURNAL, 1917, ii, p. 650). It serves another purpose in enabling one to follow the progress of a case. On finding brisk pathological regeneration in a potman some months after leaving work with colic and limp hands, I convicted him of continued indulgence. He disappeared for some months, to return with double wrist-drop, albuminuria, and brisk pathological regeneration. His protestations suggested to me that possibly a second unknown source of poisoning existed, and I advised him to leave the district. This he hesitated to do, and a few weeks after was taken, comatose and convulsed, to Isleworth, where he soon died. In conclusion, I suggest that diagnosis should depend, not on gross signs, but on appreciation of suspicious symptoms and investigation of blood and urine. Whereas examination of the urine is a tedious process, the blood film is quick, easy, and almost as reliable. I can testify that early diagnosis will avert gross symptoms, so that in a month Government referees will reject cases still showing blue line on the gums, punctated erythroblasts in the blood film, and lead in the urine.

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ULCERATIVE STOMATITIS IN CHILDREN, AND ITS TREATMENT.

DURING the war a form of stomatitis was described the causal organisms of which were the Vincent spirochaete and the fusiform bacillus; to this the name of "trench mouth" was given. This form of stomatitis has long been described in books on children's diseases under the term "ulcerative stomatitis." The treatment, however, which was extremely successful for "trench mouth" has not been applied, so far as I am aware, to children up to the present. This disease, which usually occurs after the primary dentition is well advanced, is common among the hospital class of patient, and is characterized by swelling, redness, oedema, and extreme tenderness of the gums round about the teeth. The gums may show actual ulceration. Those parts of the cheek which come in contact with the ulcerated areas may themselves show infection. The teeth are frequently carious; pressure on the gums may or may not cause pus to appear at their margins. The tongue is coated and the breath fetid; the temperature is generally raised to 101°; the child refuses food, and there may be swelling and tenderness of the lymphatic glands beneath the jaw at its angle.

Smears of the pus will usually show the fusiform bacillus and the Vincent spirochaete. The clinical picture is thus very like that of the so-called "trench mouth." The treatment which I have carried out in a large number of out-patients is as follows: The following mixture was applied to the mucous membrane of the gums, cheeks, and tongue at six-hourly intervals: liquor arsenicalis 2 drachms, vin. ipecac. 2 drachms, glycerin 2 drachms, aq. menth. pip. to 1 oz. As this mixture is poisonous, and could not be used as a mouth wash in small children, I ordered it in the following fashion: 15 drops diluted in 2 drachms of water were to be applied by means of a soft piece of muslin on the end of the finger or a camel's-hair brush. In children old enough to use this mixture as a mouth wash—that is, old enough to spit out the mixture after its application—a soft boiled toothbrush was used, a few drops of the mixture undiluted being applied to the gums by the toothbrush. The arsenic seems to be specific for the spirochaete and the vin. ipecac. for the fusiform bacillus.

In conjunction with this treatment, which was that recommended during the war for "trench mouth," potassium chlorate was administered, 12 grains in the twenty-four hours being given to children under 1 year, and 18 grains in the day to children under 2 years. In the administration of the potassium chlorate the child's meals were carefully

avoided, as it was found to tend to produce indigestion. Attention was paid to the general condition of the child, the diet being nutritious, and plenty of fresh air and fresh fruit were indicated.

The improvement with this treatment was rapid, the acute symptoms subsiding in thirty-six hours. There is, unfortunately, a tendency for this condition to recur. As it is extremely infectious, care should be taken to prevent other members of the family contracting the disease. Very often in my cases I found that one of the parents was suffering from the disease and had probably been the source of the infection.

DONALD PATERSON, M.B., M.R.C.P.,  
Physician to Out-patients, Children's Hospital,  
Great Ormond Street.

### ERYSIPELAS OF THE MOUTH.

Cases of erysipelas attacking the fauces are somewhat rare, and worthy of record.

Recently Mrs. L. was notified as a suspected case of diphtheria, but her throat had not been well seen by her medical adviser; he, however, gave her 2,000 units of antitoxin, and, as she was obviously very ill, requested her removal to hospital.

I saw her there; she had then been thirty-six hours ill, complaining of sore throat, a feeling of swelling in the throat, and difficulty in opening her mouth; the temperature was 104°; she was seven months pregnant. There was some enlargement of the cervical glands; her throat was congested and dark in colour; the fauces and tongue showed bullae. The next day the throat appeared somewhat better, the bullae on the tongue had burst, and ulcers to the number of about a dozen were counted on her tongue; there was some nasal discharge, and the temperature remained raised. When ill seventy-two hours the infection passed by way of lips and nose to the face, thence to the body, and finally ceased at the costal margins. Profuse desquamation ensued. The ulcers on the tongue gradually improved as the sloughs separated, and confluence followed; pregnancy was not interrupted, and there were no complications.

Assistant M.O.H. Sunderland.

## Reports of Societies.

### THE PRESENT POSITION OF ORGANOATHERAPY.

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on January 9th, with the President, Dr. W. LANGDON BROWN, in the chair, a discussion took place on the present position of organo-therapy.

Professor SWALE VINCENT began with a criticism of the groundless and fantastic theories which surrounded this subject. It seemed that neither the scientific discrimination of the medical profession nor the common sense of the general public could yet be trusted. The doctrine and practice of organo-therapy appeared to involve the therapeutic use of practically every organ and tissue in the body. Many foolish notions were abroad—one, for example, was that a preparation from the pancreas, tonsil, and duodenal mucosa, taken by the mouth, was a remedy for diabetes. A large number of substances were recommended for administration by the mouth, which, so far as could be discovered, produced no physiological effect of any kind when given in that way. He thought that when physicians insisted on giving substances by the mouth they should be called upon to defend their practice by proper clinical records of their cases. Substances which produced no effect when given by the mouth might have certain effects when given subcutaneously, but even then the effects were not specific, and were at best only temporary. In the whole province of therapeutics there were many fallacies and pitfalls, in particular the one expressed by *post hoc, ergo propter hoc*. It was truly said that it was a poor cure which never found its lucky patient. For various reasons, most of them obvious, treatment was often undertaken just at the time when things were at their worst, so that a turn for the better was put down to the credit of the treatment. Many patients recovered without treatment at all; when treatment was given it was by no means always certain that it had anything to do with the recovery, and in some cases the position might be that recovery took place

in spite of treatment! But it seemed clear that, if the value of a remedy was to be ascertained and demonstrated, something like a series of experiments must be carried out. It would be presumptuous on his part, as one not in practice, to point out how a clinical worker should conduct his experiments, but at any rate the necessity of adequate and rigid controls should be urged. The endless records of single cases alleged to have been cured by this or that drug were not worth the paper on which they were written. That was true of general therapeutics, and truer still of organo-therapy.

Passing to a more particularized review the speaker said that the value of thyroid preparations in myxoedema appeared to be established, and these preparations might be valuable under certain other conditions—in some cases of goitre, for instance, and in obesity. Many observers asserted that thyroid did good in quite a wide range of conditions, and it was, of course, conceivable that a drug which stimulated the chemical activities of the body might have many indications. Parathyroid had been used in different conditions, with very uncertain results; here he thought the most optimistic endocrinologist would make no very large claims. It had never been shown that treatment with pituitary extract had the slightest effect in remedying the symptoms due to pituitary insufficiency. The value of adrenaline medication bore a very problematic relation to the adrena function, and here again, as in the case of extracts of the posterior lobe of the pituitary, there was no such thing as substitution therapy. In Addison's disease adrenaline preparations did not seem to be of the slightest value. As for testicular and ovarian medication, it was doubtful whether such preparations produced any effect when administered by the mouth; when administered subcutaneously a mild stimulant or irritant effect might be observed, which, however, was not specific, but was produced by many other substances. It was generally recognized that the pancreas furnished an internal secretion the elimination of which might give rise to a condition resembling the disease known as diabetes, but the administration of pancreatic extract had not been proved to be of any value in that condition. During recent months, however, the investigations undertaken at the University of Toronto (BRITISH MEDICAL JOURNAL, November 4th, 1922, p. 833, and November 18th, p. 991) made it seem necessary to revise this judgement. It would not be wise to be too sanguine, but it was not out of the question that, sooner or later, there might be a preparation from the pancreas which would have the same action in diabetes as thyroïd had in myxoedema.

To sum up, if the search was for a true substitution therapy—the artificial replacement of an internal secretion—the reward was the solitary instance of thyroïd, though it might be that before long the pancreas must be added. There were also a few instances in which substances were valuable as drugs, apart altogether from any question of the internal secretions—for example, adrenaline. On no subject was such utter nonsense talked as on the internal secretions, and organo-therapy, or a large portion of it, might be defined as the application of this nonsense to practical medicine. In the meantime certain firms of manufacturing druggists were growing rich owing to the ignorance of the public and the lack of discrimination of the medical profession.

Professor G. R. MURRAY (Manchester) thought that a discussion on organo-therapy at the present time would serve a very useful purpose. Certain lines of treatment by this means were based on sound physiological principles, although, owing to the enthusiasm of speculative writers, a great deal of ephemeral literature had appeared on the subject, much of it of no value, and some of it positively harmful. The term "organo-therapy" might include the products of the secretory, excretory, and the incretory glands. The excretory glands, from the nature of their function, did not promise much help, though urea might be mentioned. The secretory glands were those which delivered their secretion through a duct to the surface of the skin or mucous membrane; the incretory or endocrine glands discharged their secretion into the blood, lymph, or cerebro-spinal fluid. He would confine his remarks to conditions in which the treatment was of value in clinical medicine. The first and most important use of the thyroïd preparation was to supplement a failing thyroïd gland, which, owing to fibrotic atrophy or other destructive lesion, could no longer provide even the minimum amount of hormone necessary. If a case failed to respond to the treatment it might be well to change the preparation, for he had come across preparations which had no activity at all, probably owing to some fault in the manufacture of the

particular sample, or possibly to the selection of the wrong gland—a contingency always to be borne in mind. When thyroid treatment was started there was a latent period of a week or more before any definite effect was observed. If any signs of hyperthyroidism were present, the use of thyroid extract was contraindicated, and this was an important point to observe before starting treatment in cases of simple goitre; as a rule, the pulse rate would give the indication. In simple obesity he had seldom found it beneficial unless combined with special dieting. In some menstrual disorders a beneficial action had followed quite small doses, and in tertiary syphilis also good results had been obtained. The function of the parathyroid glands had been under discussion for years; here he had had no personal experience. With regard to the suprarenals, it was known that Addison's disease was due to a destructive lesion of the glands, but the administration of whole adrenaline or any preparation of it was quite unable to revive the glandular function. He had never seen permanent improvement in Addison's disease by this treatment, though in other respects adrenaline presented an extremely valuable remedy on account of its action on the sympathetic nervous system. He had found it of value in the treatment of oesophageal spasm; it seemed as if the adrenaline was held up by the oesophagus, where it exercised possibly some local action, as very often immediately after a dose patients could swallow food with comfort. Extract of pituitary gland, given subcutaneously, was a valuable remedy. Its careful use had a well recognized place as a uterine stimulant in obstetric practice; it had been found useful also in the treatment of diabetes insipidus. Little evidence was available to show that either testicular or ovarian preparations had any value when taken by the mouth, and there was no clear proof that eunuchism could be removed by testicular preparations. The active principle of pancreatic secretion had long been sought, and the recent achievements of Banting and Best at Toronto were of great interest and encouragement. On the whole, it might be claimed that preparations of thyroid, parathyroid, pancreas, suprarenal, and pituitary glands were agents of value, though in other cases it could not fairly be said that it was known how to obtain or employ satisfactory preparations. The recent exploitation of organo-therapy was deplorable, because it tended to discredit the proper use of these substances.

In acknowledging the President's thanks for having come from Manchester specially to address the Section, Professor Murray said that he felt that the work of the pioneers in organo-therapy should always be gratefully acknowledged; he referred in particular to the work done by Sir Victor Horsley, who in the early days had shown the relation between thyroid and myxoedema.

#### *The Clinical Use of Parathyroid.*

Dr. W. R. GROVE (St. Ives) brought forward some clinical results of the administration of parathyroid, but he said that he did so with considerable trepidation after the remarks of Professor Swale Vincent. Nevertheless, his cases had been followed up very closely. His attention was drawn to parathyroid after he had been engaged over a long period in the study of calcium metabolism. In 1906 a colleague informed him of the good effect clinically of calcium salts in ulcers and other conditions. He confirmed these results in ulcers, and also in some eczemas. He also injected intramuscularly calcium chloride in single grain doses, diluted 1:100, for haemorrhages which could not be reached surgically. Therefore he came to the subject of organo-therapy already a firm believer from clinical evidence in the effects of the administration of calcium salts both by the mouth and intramuscularly. Dr. Vines of Cambridge, who knew of his interest in calcium metabolism, asked him to collaborate with him from the clinical side in certain investigations.

The first case taken was a woman, aged 55, prematurely old, with a large varicose ulcer of the leg. She was calcium deficient, and on calcium chloride being given intramuscularly at weekly intervals the calcium content of the blood increased, though it never reached more than 80 per cent. of the normal, and an improvement in the ulcer synchronized with the higher calcium content of the blood. The injections were stopped for three weeks while calcium was given by the mouth, and the ulcer then increased in size.

Some half-dozen other cases, all of them showing calcium deficiency, were by this time under treatment, and all of them improved with intramuscular injections, though they never reached normal, while calcium by the mouth was followed by no signs of improvement in the blood, and very little in the ulcer. It was in this series of cases that the administration

of parathyroid was then begun, in 1/10 grain doses daily. In every case the blood rapidly became normal, never taking more than a fortnight to do so, and the ulcers started healing. At the end of five weeks from the commencement of the parathyroid treatment the first and most obstinate case, in which the ulcer had completely encircled the leg, and which had gone on with varying results for two hundred days under calcium chloride treatment, was completely healed, and in the smaller ulcers in other cases the healing was still more expeditious. A number of related conditions had been tried and had yielded good results under parathyroid treatment. These included bed sores and severe burns. All diseases in the rheumatic group invariably showed calcium deficiency, and in every case of this kind treated there were undoubted signs of improvement after administration of parathyroid. A gumma of the face gave a remarkable reaction to parathyroid after the case had resisted ordinary antisyphilitic treatment for months. Another striking success was in a case of herpes zoster of the conjunctiva with iritis. In pernicious anaemia there was a hopeful field. He had also seen about a dozen cases of enlarged prostate, all with calcium deficiency, which had shown most striking results on treatment with parathyroid. One patient who had lived a catheter life for three months was able to do without the catheter, and was only disturbed once or twice in a night. It seemed to him that calcium deficiency was an index of the absorption of a toxin, and that many chronic diseases were due to the breakdown, in consequence, of the defences of the body, the controlling mechanism being situated apparently in the parathyroid glands. If the focus of the disease itself could not be removed, parathyroid was only an alleviative agent, but nevertheless a valuable one.

Dr. HOWARD VINES (Cambridge), who was asked to supplement Dr. Grove's account of his work, said that in all these cases in which good effects were observed in parathyroid treatment the underlying condition was sepsis, which accounted for a large number of the diseases set out in separate paragraphs in the medical textbooks. In three or four cases he did white blood counts during the period of parathyroid treatment, and found the polymorphonuclears go up considerably, along with the improvement in the patient's condition. Parathyroid brought about a stimulation of leucocytic activity; he did not suppose that this had anything to do with a direct action of the parathyroid substance on the leucocyte-producing centres, and it seemed to him a much more rational idea that it was brought about by the calcium of the blood plasma. Dr. Grove's statement of cases might sound as though a panacea had been discovered, but the story at bottom was simple: it was a matter of increasing the physical resistance to bacterial infection.

#### *The Action of Ovarian Extract.*

Dr. W. E. DIXON (Cambridge) gave an account of some work not yet published. He said that Harvey Cushing first made the observation that pituitary extract was secreted into the cerebro-spinal fluid. Thereafter three or four other observers stated definitely that they had not been able to find pituitary present in that fluid. Experiments on this point in his own laboratory were performed principally on dogs and on a few cats. A cannula was put into the cerebro-spinal canal high up, all the experiments in which the cerebro-spinal fluid was blood-stained were discarded, and the action on the guinea-pig was tested, every known test being made for pituitary. In the result they succeeded in obtaining pituitary extract in the cerebro-spinal fluid in practically every instance. Different specimens of the fluid yielded different amounts, which was not extraordinary, because the needs of the body would naturally determine the amount present. The object of the experiments was to determine what substances could increase the action of pituitary in the cerebro-spinal fluid. Here the experiments yielded a mass of negative results, and the only substance which invariably produced an increased secretion of pituitary immediately (the secretion only lasted from one to two minutes, after which the normal condition was resumed) was ovarian extract. The ovarian extract was boiled and filtered, and the filtrate injected into a vein. The cerebro-spinal fluid, which was being collected all the time, immediately after this injection produced an increase—in some cases a very large increase—of pituitary extract. Orchitic extract did not produce any effect, but extracts of duodenum or small intestine, boiled and filtered in exactly the same way, similarly increased the secretion of pituitary extract, though not immediately; there was a long delay—perhaps an hour—before any marked increase in the

pituitary secretion took place. One naturally looked to the alimentary canal for an explanation of this phenomenon. The first suggestion was that it might have something to do with facilitating absorption from the alimentary canal, but there was no increased absorption at all. The absorption remained quite constant, but he noticed that pituitary increased the tone of the whole intestine.

Dr. W. LANGDON BROWN said that the discussion had been most interesting, none the less because Professor Swale Vincent had opened it with a refreshing dose of scepticism. It was quite time that they should be reminded of the need for studying the underlying physiological basis for all this work, and should take a little more careful stock of the evidence for and against any particular diseases being associated with endocrine defects and of their possibilities of remedy by organotherapeutic means. Organotherapy was lagging some way behind the observations made in endocrinology. It must be admitted that the basis upon which the clinical observations had been made was in many instances not as satisfactory as could be wished. At the same time the observations which Dr. Grove and Dr. Vines had brought forward that evening showed that evidence was available by clinical means, apart from ordinary physiological laboratory experiments, which would meet all the tests that could be asked of it. The observations mentioned by Dr. Dixon were very important as showing that there was something in the ovary which definitely stimulated the pituitary gland. Therefore he did not think one could possibly take up so negative a position as Professor Swale Vincent had done. Professor Vincent had carried the negative position too far. The speaker went on to refer to the observations on glycosuria in pregnancy, where the blood-sugar curve, demonstrated by Mackenzie Wallis, had been shown to be exactly the same type of curve as the one given in pituitary lesions, suggesting again some connexion involving ovary and pituitary. He mentioned two cases in which he had used ovarian extract, and in which the evidence pointed to a definite effect.

A woman, aged 20, had an artificial climacteric induced by the removal of both ovaries and tubes for tuberculous disease. She began to put on weight, which was not unexpected, and she had choking, with quickening of pulse lasting about six minutes, and epilepsy. Her thyroid swelled up during the attack, and she passed a little sugar after the attack.

She was given ovarian extract, and whereas she had previously had three or four attacks a week she had had only one attack since last Easter. This patient was first observed under hospital conditions; she did not know what she was taking, and no attempt was made to suggest strongly that it was going to have a remarkable action.

The other case was one of thymic asthma. A number of remedies had been tried, and the attacks continued to be quite frequent. After ovarian extract was given they became less frequent, and were now rare.

He did not think there was any improbability in the supposition that some preparations of ovarian extract had therapeutic effects, but he himself had approached this question as a sceptic, and he still recognized that it was necessary to look to the basis of the clinical observations very thoroughly.

Professor SWALE VINCENT said that he had given in his paper a list of a large number of drugs which, he suggested, were useless or practically so. The only one in that list which had been challenged in the discussion was parathyroid, about which very little was known. He could not discuss the clinical evidence in its favour brought forward that evening, but his general thesis, which he still maintained, was that he would not expect anything to produce a pharmacological effect which had no physiological action. A man could not be cured by any means which would not also kill him. In the case of thyroid there could be "kill" as well as "cure." In the case of parathyroid he still—humbly, as became one not engaged in practice—reserved his opinion until a number of other cases were available. As for ovarian extract, this was the first time he had heard it authoritatively stated that ovarian extract had any effect which could not equally be got out of the big toe or any other part of the body. The President had hinted that he (Professor Vincent) did not give due credit to clinical observations. All he had said was that clinicians would have to be a little more scientific in the way they gave their evidence. Proper controls often were not taken, and the records furnished no idea of the precise conditions under which the treatment was given. He would not presume to deny that results followed

the use of ovarian extract. He only took the liberty of saying that they were not proven on the evidence which so far he had had an opportunity of examining.

### CHRONIC INTUSSUSCEPTION IN CHILDREN.

A MEETING of the Liverpool Medical Institution was held on January 4th, with the President, Professor J. HILL ABRAHAM, in the chair, when Mr. R. C. DUN read a note on chronic intussusception in children. He referred to ten cases, all of which were operated on and recovered. In no case was there any difficulty in reduction and no adhesions were found. The average age of the children affected was 5 years. The duration of symptoms was from four weeks to two and a half years. An abdominal tumour was felt in six out of the ten cases. Blood and mucus were passed per rectum in only two of the cases, and in no case was complete obstruction reached. In none of the cases was any definite pathological condition found which would account for the formation of the intussusception.

Mr. J. T. MORRISON, referring to two cases recently seen by him, said there were cases with borderline symptoms between the acute and chronic types. One such, a boy aged 18 months, having previously had a typical ileo-caecal acute intussusception, was again seized with a similar attack. Operation showed a pure colic intussusception easily reducible and without oedema or congestion. The other case, a boy aged 5 years, had symptoms of acute obstruction of a definite but not very severe type, necessitating immediate operation. There was no blood or mucus, but a vague tumour was present in the right side of the abdomen. Previous health had been excellent. At operation a very easily reducible intussusception of the ileo-caecal type was found. There was practically no oedema of the apex. During convalescence he had an attack of fever (104°) of one day's duration, with blood and mucus in the stools. Otherwise there were no further symptoms. Was this, he asked, an abortive attack of intussusception or merely an attack of enteritis?

### Night Blindness.

Mr. H. HAWARD BYWATER read a short paper on night blindness. He divided the subject into two groups: (1) the congenital and hereditary forms, (2) the acquired varieties. The first group comprised the rare congenital form with normal fundi, which was stationary, and the three hereditary conditions: (a) retinitis pigmentosa (and its non-pigmentary form), (b) retinitis punctata alba, and (c) gyrate atrophy of the retina and choroid (which were progressive). The second group comprised: (a) acquired retino choroiditis (syphilitic, which became stationary if treated), (b) epidemic night blindness (this, the most important form, might or might not be associated with xerosis of the conjunctiva), and (c) physiological night blindness of the one eye, as described by Thomson Henderson. After giving reasons why myopia and hypermetropia had difficulty at night, Mr. Bywater gave particulars of seventy cases of night blindness seen in Salonica by Major Usher and himself in 1917, with the tests applied. He mentioned that fourteen out of seventy were men who had useful vision only in one eye; he also described cases of the epidemic form occurring in miners during the last coal strike and xerosis in children. After briefly discussing the theories of night blindness he described experiments to prove that visual purple formation was carried out by the eye itself independent of the central nervous system. Changes in the visual purple appeared to be due partly to ultra-violet rays of greater length than 300 microns and partly by rays of the visual spectrum. Experiments to show the protection given by the media of the eye against the harmful rays of bright light were described; finally, the diagnosis and treatment of the different varieties were summarized.

Dr. A. E. BURNHOUGH considered the most interesting aspect of night blindness was the congenital stationary type—that in which night blindness existed along with no other apparent abnormality of the eyes. This was purely hereditary and occurred in families often throughout many generations. A very full account, giving very extensive family trees of affected families, had recently been issued from the eugenics laboratory of Professor Karl Pearson. A type had appeared in which the female members of a family escaped but passed it on to the males. The affection was supposed to be rare, and in its higher degrees he believed it was so, but he had come across many cases of modified congenital stationary night blindness, especially noticeable during the time of the lighting restrictions in the war.

Dr. T. W. WADSWORTH described a case of syphilis of the lung. The patient was aged 17 years, and complained of cough and slight expectoration for six months. She was poorly nourished, her fingers clubbed, incisor teeth notched, the Wassermann reaction positive, the sputum negative as regards tubercle bacilli. There was an area of dullness just below the inferior angle of the left scapula. The breath sounds were bronchial in this area, and there was pectoriloquy and crepitations. X-ray examination of the chest showed a shadow corresponding to the area found clinically. After treatment with iodides and mercury and an injection of 0.3 gram novarsenobenzol the physical signs cleared up, and x-ray examination of the chest demonstrated that the opaque area had almost vanished. From the evidences of syphilis, the absence of tubercle bacilli, and the response to treatment, the diagnosis was established.

Dr. A. DOUGLAS BIGLAND read a note on the diagnosis and treatment of migraine, in which he advocated the administration of calcium salts.

### DIATHERMY IN SURGERY.

At the last meeting of the Brighton and Sussex Medico-Chirurgical Society Dr. H. T. CUBBON read a paper on the use of diathermy in surgery. He gave a general outline of the physical effects produced by the passage of the diathermy current through the body, with special reference to the destruction of morbid tissue by the heat produced. Specimens of meat were shown in order to demonstrate this. Dr. Cubbon then gave a short description of the technique of a diathermy operation. The destruction of tissue by diathermy being the result of coagulation, there should be no haemorrhage; this was a great advantage to the patient and surgeon. The risk of haemorrhage was dealt with and the means of avoiding it by careful attention to technique.

The advantages of diathermy over ordinary surgical procedures were summarized and discussed under the following headings:

1. Lack of primary haemorrhage.
2. Absence of shock and pain.
3. Relief of pain in palliative operation.
4. Diminished risk of cell implantation.
5. Sterilization of the parts operated upon by the heat produced.
6. Firmer, denser, and more pliable scar from diathermy, with less tendency towards breaking down.
7. The method of choice in patients too old or feeble for operation by other methods.
8. The patient more willing to undergo further applications where necessary, because of the simplicity of the operation and the few after-effects.
9. Rapid convalescence.

The complications which might arise after diathermy operations were discussed; these included oedema and risk of obstruction in laryngeal operations and risk of secondary haemorrhage. Practically all cases of malignant disease involving the tongue, the floor of the mouth, palate, fauces, and certain parts of the pharynx, vagina, and vulva were suitable for diathermy. Fibromata of the nasopharynx, papillomata of the bladder, cavernous naevi of the tongue, lips, pharynx, and buccal mucous membrane were cited as non-malignant pathological conditions which could be destroyed by diathermy with excellent results. Dr. Cubbon added that warts and small pigmented areas of skin could be effectively destroyed by diathermy sparks; strictly speaking, this was not diathermy, but the sparks produced by the diathermy auto-condensation method were so much less painful than the older high frequency sparking that very often tissue could be destroyed without the use of a general anaesthetic. Most of the cases of malignant disease which had been operated upon by diathermy were those considered inoperable from the ordinary surgical standpoint. These cases had been naturally far advanced and cures could not be expected, but in spite of that the results had been distinctly encouraging. In operating on all early cases of malignant disease of the mouth and upper air passages diathermy, in view of its advantages, should be considered the method of choice. Diathermy was no more a specific for the cure of malignant disease than operation, but a combination of the two would be an immense help to the surgeon.

Mr. M. FITZMAURICE-KELLY showed four cases, all of which had been successfully treated by diathermy by Dr. Cubbon and himself.

Mr. ROBERT SANDERSON read notes of a case of subinvolution of the uterus, and of a case of malignant annular stricture of the colon.

## Reviews.

### THE ADMINISTRATION OF ANAESTHETICS.

THE fourth edition of Hewitt's *Anaesthetics and their Administration* was published in 1912 before the lamented death of its original author, and it is timely and fitting that the work should be brought up to date in view of the general advances made both in the scientific and in the practical part of the art of anaesthesia during the past few years. Dr. HENRY ROBINSON, who was also the editor of the last edition under the immediate personal supervision of the late Sir Frederic Hewitt, is now entirely responsible for the clinical chapters, and has almost entirely rewritten them. Mr. Digby Cotes-Preedy has again contributed the chapter on the medico-legal aspects of surgical anaesthesia, and Dr. A. J. Clark, Professor of Pharmacology at University College, London, has now undertaken the responsibility of revising the two chapters dealing with the physiology of anaesthesia.

The book commences, as formerly, with a chapter on the evolution of surgical anaesthesia; the second chapter is devoted to the properties and impurities of the chief agents capable of producing general surgical anaesthesia. The selection of anaesthetics, the extraneous circumstances of anaesthetization, and the use of morphine and other alkaloids in conjunction with anaesthetics are then considered. After accounts of the administration of the principal anaesthetics, mixtures of general anaesthetics are discussed; sequences and alternations of general anaesthetics are next described, and then local and regional anaesthesia. Spinal anaesthesia has a chapter to itself; minor difficulties in anaesthetization, the cause and treatment (preventive and immediate) of respiratory arrest and of circulatory failure, and the after-condition of the patient are discussed, and an adequate index has been provided.

The chapters devoted to the physiology of anaesthesia are a masterly synopsis of a difficult subject. Professor Clark has succeeded in making interesting a subject which tends to be "dry" as well as difficult. His explanations are clear and concise, and his illustrations equally clear and well chosen. After defining anaesthetics he discusses the six theories as to their mode of action, and comes to the conclusion that the drugs act by decreasing the permeability of the cells, though the exact mode of this action is still uncertain. He deals next with the absorption, excretion, and distribution in the body of anaesthetics, and, after touching on shock and its treatment, brings his excellent little monograph to a close by consideration of each of the principal anaesthetics in turn.

For the work of the general editor we have nothing but praise, even though we are inclined to quarrel with him over minor points. For example, on page 143 the case reported by Dr. Guthrie really has nothing to do with the question of nitrous oxide and ether in cases of cardiac affections mentioned in the previous paragraph, though the juxtaposition of the two paragraphs makes it appear as though there was some connexion. Again, he recommends on page 257 the addition of rubber cushions to Trewby's apparatus for combined nasal and oral administration of nitrous oxide and oxygen, thereby doing away with one of the claims the inventor made for his instrument, that of being readily cleansed even by boiling; it is an addition which is, in practice, rarely necessary if the nose and mouth pieces are properly made. It is also a blemish that the instrument figured is not the one used for nitrous oxide and oxygen administration as stated beneath the illustration, but the one for nitrous oxide and air. Omissions are few, but in a future edition it might be as well to figure the double bottle modification of Junker's inhaler, in which, no matter how the connecting tubes are joined up, chloroform cannot reach the patient in the liquid state.

The book is excellently printed on good paper, and the illustrations throughout are adequate and well reproduced. Altogether it can be recommended both to the practitioner and the student.

<sup>1</sup> *Anaesthetics and their Administration*. A textbook by the late Sir Frederic W. Hewitt, M.V.O., M.A., M.D. Fifth edition. Edited by Henry Robinson, M.A., M.D., B.Ch. Oxford Medical Publications. London: Henry Frowde, and Hodder and Stoughton. 1922. (Demy 8vo, pp. xiii + 576; 83 figures. 30s. net.)

## SURGICAL ANATOMY.

THE second edition of the excellent *Manual of Surgical Anatomy*<sup>2</sup> by BEESLY and JOHNSTON differs only slightly from the first. The section on nerve injuries has been rewritten, and provides a useful summary of the recent advances in this subject; a few other additions and alterations in the letterpress and in the illustrations have been made. As was said in the review of the first edition, the authors have succeeded in compiling a full but concise account of the surgical anatomy required for the higher examinations; and the popularity of the book with students and graduates proves that it has fulfilled its purpose. The arrangement follows the plan of Cunningham's *Practical Anatomy*. The book is intended by the authors to be used in the dissecting room; but it will be found just as interesting and clear to read in the study. The sections on joints are really excellent, and the description of the anatomical relations of the joints in disease, and the various ways of surgical approach, is the most illuminating that we have read in a small textbook; we especially commend the pages dealing with the knee-joint and its derangements. The illustrations, many of which are familiar, are clear and to the point, and the printing is excellent.

The third edition of the *Manual of Surgical Anatomy*,<sup>3</sup> by Mr. CHARLES R. WHITTAKER of Edinburgh, has been considerably enlarged, and the number of illustrations has been more than doubled. Considerably more attention is paid to the anatomical descriptions, which are excellent, than to surgery. There is, indeed, throughout the book a lack of emphasis on the surgical applications to anatomy. The manual is full of tables and diagrams, all of which are clear and should prove useful. The print is large and clear, and there is an efficient index. This book should serve its purpose of helping the student in revising his work for his qualifying examination.

## VISCERAL NEUROLOGY.

THE first edition of Dr. F. M. POTTENGER'S *Symptoms of Visceral Disease*<sup>4</sup> was reviewed in the BRITISH MEDICAL JOURNAL in 1920 (vol. ii, p. 861). A second edition has now appeared in a somewhat expanded and modified form. Though for more than twenty years devoted to the study of chest disease the author pleads for the unity of medicine and deprecates specialism, whether of the laboratory, such as bacteriology, metabolism, and biochemistry, or clinically of particular parts of the body, and insists that the great requisite of modern medicine is accurate clinical observation and interpretation carried out with the same care that the laboratory worker has developed in his department of work. Emphasis is also laid on the need to pay attention to the individual sufferer and not only to the "disease which has the patient." In many respects this argument resembles that of Sir James Mackenzie, but Dr. Pottenger came independently to the conclusion that most symptoms are due to altered nerve and endocrine activity. Disease expresses itself physically and psychically: physically mainly by reflex action through the vegetative nervous system, some stimuli acting chiefly on the sympathetic and others on the parasympathetic division; psychological disturbance, depending on fatigue and irritability of nerve cells, occurs in both acute and chronic diseases and is shown by neurasthenia and psychasthenia.

A rational classification of the symptoms of inflammatory affections of the viscera is suggested under the heads of those due (1) to toxæmia, such as malaise; (2) to reflex action—for example, cough in pulmonary tuberculosis; (3) to the disease *per se*; and (4) those appearing when the disease is well established; this grouping emphasizes the unity of the body, the interrelationship of the various viscera, and the widespread disturbance that may follow a single stimulus. The visceral reflex is discussed and two chapters are devoted to reflexes, the afferent impulses of which course in the

sympathetic and in the parasympathetic nerves respectively. Stress is laid on the viscerotrophic reflexes, and as an example of those due to the sympathetic the muscular wasting of the chest wall in pulmonary tuberculosis is given. The interesting suggestion is made that tuberculous infection of the larynx, which is most apt to occur on the side corresponding to the lung mainly affected, is favoured by the parasympathetic reflex. The author describes the sympathetic system as protecting the individual against outward enemies, whereas the parasympathetic maintains the organism as an individual. The syndromes of these two portions of the vegetative nervous system are then briefly sketched. In the third part of the book, which deals mainly with the anatomy and physiology of the vegetative nervous system, the opinion is expressed that too much stress has been laid on the effect of adrenaline, atropine, pilocarpine, and other drugs in the differentiation of vagotonia and sympathicotonia. The second and larger part of this work deals seriatim with the nerve supply of the viscera and touches on the clinical aspects of the more important viscerogenic reflexes. The author has evidently worked hard at a difficult subject, and, though the book, as pointed out in our review of the first edition, is not attractive to read, it cannot fail to be useful as a source of reference.

## PHYSICAL METHODS IN THE TREATMENT OF CIRCULATORY DISORDERS.

PHYSICAL methods in the treatment of diseases of the circulatory system have never been so popular in this country as on the Continent or in America, though graduated exercises have been extensively used in the treatment of the effort syndrome. Drs. MATHIEU, RICHARD, and HARANCHIPIY, in their little book on the treatment of cardio-vascular diseases by massage, movements, and other physical agents,<sup>5</sup> state that, while many of the larger treatises on medicine recommend these methods, few give sufficient details, and the practitioner is thus apt to hand over his patients to those who specialize in this line. The book is intended to obviate this, and to suggest methods which can be adopted without the aid of a trained masseur or of any elaborate apparatus.

After a brief summary of the physiology of the circulation and the general effects which might be expected to follow from mechanical measures, the main portion of the book deals in detail with the technique and application of the various forms of massage, passive and active movements, hydrotherapy, electrotherapy, and of heat and light baths, in their relation to the circulation. The instructions are given in clear and lucid terms so that anyone making use of these forms of treatment will not be left in doubt as to the authors' intentions. In the concluding part of the book various cardiac and vascular disorders are discussed and the appropriate therapy suggested.

One hesitates to share fully the optimism which seems to be possessed by the writers in anticipating the results of their methods; but the book itself is well worthy of perusal by those who are interested in this branch of medicine, and fills a useful gap in knowledge.

## NOTES ON BOOKS.

THE issue of a fifth edition of Mr. CLAUD WORTH'S book on *Squint*<sup>6</sup> is sufficient evidence of its usefulness. It is deservedly well known as a clear and sufficient statement of the general conditions which bring about this deformity and detect of vision, and the means which may be adopted to correct it. This latest edition does not differ materially from the earlier. The author emphasizes his experience that "of the cases of squint in which efficient treatment is carried out from the first appearance of the deviation, only a small proportion will ever need operation. Operation is required in the majority of the neglected or inefficiently treated cases." He records an alteration in his methods: he now seeks to obtain the full effect he desires by advancing one muscle only, and considers that the combined operation, that of advancing one muscle with tenotomy of the antagonist, is unsatisfactory. He discusses newer methods, such as folding or reefing, and partial tenotomy, but is not favourably impressed by them.

<sup>2</sup> *Tratamiento de las Maladies Cardio-vasculaires par le Massage, le Mouvement et les Agents physiques*. By Drs. P. Mathieu G. Richard, and Haranchi. Paris: Librairie Octave Doin. 1922. (Cr. 8vo. pp. 147; 1 figure. Fr. 5.)

<sup>3</sup> *Squint: Its Causes, Pathology, and Treatment*. By Claud Worth, F.R.C.S. Fifth edition. London: Baillière, Tindall, and Cox. 1921. (Demy 8vo. pp. 232; 42 figures. 12s. 6d. net.)

<sup>1</sup> *A Manual of Surgical Anatomy*. By L. Beesly, F.R.C.S. Edin., and T. H. Johnston, M.B., Ch.B. Second edition. Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton. 1922. (Cr. 8vo. pp. xiv+551; 160 figures. 18s. net.)

<sup>2</sup> *A Manual of Surgical Anatomy*. By C. R. Whittaker, F.R.C.S. Edin., F.R.S.L. Third edition, revised and enlarged. Edinburgh: E. and S. 1922. (Cr. 8vo. pp. xiv+551; 160 figures. 18s. net.)

<sup>3</sup> *A Study of the Vegetative Nervous System in Clinical Medicine*. By F. M. Pottenger, A.M. Second edition. London: Henry Kimpton. 1922. (Coloured plates. 28s. net.)

It is but a little while since we noticed the second edition of *Tidy's Synopsis of Medicine*,<sup>7</sup> and now a third has appeared, testifying to the popularity of this book among students preparing for their final examination. The introduction of several new articles has added 30 pages to the work, which now consists of nearly 1,000 pages. In revising it for future editions Dr. LETHBY TIDY would, we think, be well advised to keep within that limit, since the book is not intended as a substitute for the larger treatises on internal medicine. One or two omissions, noted in our review of the second edition, have now been rectified, notably by the inclusion of an account of protein hypersensitiveness in relation to asthma and of Vincent's angina. Altogether, the work continues to deserve high praise for its comprehensiveness and accuracy and for the skill shown in arranging and compressing the material. Its success seems now assured.

When he has recovered from his surprise at being told in one and the same breath that while it is obvious that the same equipment is not suitable for all requirements, yet, none the less, an equipment can be, and frequently is, assembled which will answer all and every purpose efficiently and well, the dentist who wishes to take his own x rays will find the first four chapters of Mr. KEMPSTER'S *Dental Radiology*,<sup>8</sup> a most useful guide both as to outfit and practical working. It may, however, be pointed out that Figs. 16 and 18—"too high" and "correct" positions of tube—being printed the one across and the other along the long axis of the page, are not quite suitably arranged for comparison. A chapter is devoted to the interpretation of dental radiographs, but we fear that the dentist will not reap from its perusal as much benefit as he might reasonably expect. There seem to be too many examples of the same condition, and in too many cases we cannot make figure and description agree with each other (for example, Fig. 59.3, 61.4). The meaning of the diagrammatic figures of "pyorrhoea" on page 146 is not easy to discern. We cannot gather the difference between "periodontal thickening" and "pericemental thickening," either from letterpress or illustration. Perhaps in another edition the author will supply the deficiency of illustrations of such conditions as fracture, dislocation, foreign bodies, isolated foci of infection, exostosis, and necrosis. The two concluding chapters on localization and protection of the worker are brief but practical.

The *British Journal Photographic Almanac*<sup>9</sup> for 1923, edited by Mr. GEORGE E. BROWN, F.I.C. (the sixty-second issue), is on the same lines as those of late years. The advertisements of everything bearing on photography are such a feature of this annual that it may be truly said that nothing photographic is omitted; we should take it that every photographic firm and every photographic appliance is somewhere recorded in these pages. The list of photographic societies of the United Kingdom, it may surprise some to be told, contains the names of close on five hundred. The book proper is introduced by an article by the editor on "What camera and lens to have"; the advantages and disadvantages of all sorts of cameras are discussed and contrasted. Stated cameras, hand cameras, box cameras, reflex cameras, all are reviewed, as are plates as against film packs or roll films, the various types of lenses, their focal length, and so on; shutters, and various accessories. Shortly and concisely this article furnishes an amount of useful information which should be of the greatest help in "buying a camera." There follows an epitome of progress which deals with the events of the year, with apparatus and equipment, with lenses, and with photographic processes of all kinds. Finally, a large section deals with the formulae of developing solutions, fixing solutions, hardening and clearing solutions, negative intensifiers, and so on. No photographer, amateur or professional, can afford to be without this almanac; there is a good index, and the amount of information it contains on photographic matters is prodigious.

Dr. THOMAS S. CULLEN has collected and bound together reprints of papers by members of the Gynaecological Department of the Johns Hopkins Hospital and University published during the years 1916 to 1922,<sup>10</sup> and has provided a table of contents.

<sup>7</sup> *A Synopsis of Medicine*. By Henry Lethby Tidy, M.A., M.D., B.Ch. Oxon., F.R.C.P. Lond. Third edition, revised and enlarged. Bristol: John Wright and Sons, Ltd. London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd.; Toronto: The Macmillan Company of Canada, Ltd. 1922. (Cr. 8vo, pp. xv+585. 25s. ret.)

<sup>8</sup> *Dental Radiology*. By Christopher Kempster, M.R.C.S., L.R.C.P. London: The Scientific Press, Ltd. 1922. (Cr. 8vo, pp. 184; 78 figures. 10s. 6d. ret.)

<sup>9</sup> *The British Journal Photographic Almanac*, 1923. Edited by George E. Brown, F.I.C. Sixty-second issue. London: H. Greenwell and Co., Ltd. 1923. (Cr. 8vo, pp. 166; illustrated. Paper, 2s.; cloth, 3s.)

## THE MEDICAL RESEARCH COUNCIL.

### ANNUAL REPORT.

The annual report of the Medical Research Council for the year ended September 30th, 1922, has been issued this week.

#### Introductory.

The grant-in-aid at the disposal of the Council during the current financial year was £130,000, the same as in the preceding year; in this amount was again included the cost of the work of the Industrial Fatigue Research Board, and of the research work into mental disorders done on behalf of the Board of Control for England and Wales, and certain pathological inquiries conducted in Scotland for the corresponding authority there.

The Council has again been compelled to restrict very closely the work it undertakes or subsidizes at many points where increased development would have been highly desirable had funds permitted. Periodic conferences are now held at least once a quarter between representatives of the three departments chiefly concerned with the allocation of moneys voted by Parliament to scientific Development Commission, the Medical Department of Scientific and Industrial Research. The conferences are attended also by a secretary of the Royal Society, in so far as its interests, whether those in relation to the Government grant it receives for research or funds of other kinds, may be affected by, or have a bearing upon, policies or programmes of the three research departments.

Reference is made in the report to the International Conferences of the Health Section of the League of Nations<sup>1</sup> to further the establishment of an international system of common standards for estimating therapeutic serums and other substances used in medical practice or medical research which are susceptible of measurement only by indirect biological methods. Great Britain is alone among the great nations in having no system of standards and no machinery for selecting or adopting any standard of value for a given substance, but is still dependent on the United States or Germany. It is noted that as a result of the conference in Paris last November an agreement has been reached by which the standards formerly laid down for diphtheria and tetanus toxins (and antitoxins) by France, the United States, and Germany have been recommended for adjustment and general international adoption.

The Council has been able, speaking generally, to assist in a variety of ways the large body of research work done by devoted workers at many places. The report pertinently observes that "It is only by steady growth of the whole body of sound knowledge, through labours of which the methods and results are not easily understood and appreciated by the people, that practical fruit can be gathered from time to time in the better attainment of health under modern conditions of life and in the better control of disease. In maintaining and more effectively directing the support which they have been enabled to supply in aid of this scientific work the Council have again been under very heavy obligation for the abundant and ungrudging help they have received from the numerous scientific men who assist them in committees."

In a paragraph dealing with cancer the report states that the Council in framing its scheme of work has not encroached upon the work being done for the Imperial Cancer Research Fund and at the Middlesex Hospital, but has arranged schemes described in more detail below for the utilization at various selected hospital centres of the radium held by the Council for the Government.

The problem of the filter-passing virus is being investigated at the National Institute for Medical Research by biochemists, physicists, and pathologists, in association with work arranged at fever hospitals under the Metropolitan Asylums Board and elsewhere. Reference is made to the investigations in this direction by Dr. Gordon of St. Bartholomew's Hospital. With regard to influenza and common colds, it is observed that the latter not only regularly inflict widespread suffering and great economic loss, but have undoubtedly a very high mortality, though it be in large part concealed or indirect. One difficulty encountered in the laboratory investigation of influenza is the doubt whether the disease is transmissible to other animals than man; in this connexion the Council has made arrangements for an experimental study of distemper in dogs, which there is good reason to think offers

<sup>1</sup> BRITISH MEDICAL JOURNAL, December 17th, 1921, p. 1019; December 24th, p. 1080, and December 15th, 1922, p. 1160.

a close parallel to human influenza. Towards the cost of this investigation independent financial support is assured. This inquiry affords an illustration of the close relations between animal and human diseases. Studies of naturally occurring animal diseases have already assisted human medicine, and it is not to be doubted that their more regularized and systematized investigation by well trained and adequately paid research workers will produce results of value which at present can only be guessed. Another instance is afforded by tuberculosis; a committee of the Council has been working at improved methods for applying tuberculin tests in cattle. Again, the occurrence of the outbreak of botulism at Loch Maree last August has raised the question of its possible relation to grass sickness, which has been prevalent among horses in Scotland; work done in 1918 for the armies in France gave important guidance towards the provision of an antitoxin obtained from horses for the cure of grass sickness. The concluding paragraph of the report refers to the treatment of diabetes by extracts of pancreas, as described in our columns from the Physiological Department of the University of Toronto by Professor J. J. R. Macleod and Dr. F. G. Banting and his fellow workers. The Medical Research Council accepted the offer of the University of Toronto to control the patent rights in this country, and has taken measures for the encouragement and support of research work within the National Institute and at several hospitals in London and elsewhere with a view to making a supply of insulin available for use in this country as rapidly as possible, and promoting further improvements in its production and therapeutic use. "It must be gratifying," the report states, "to many that this success has come within one of the Canadian medical schools, of which the development and growth in recent years has been so notable, and that so conspicuous an achievement should have come from a group of young men whose eager military service during the war must at many points have brought handicap to their scientific work."

#### THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH (HAMPSHIRE).

In the Department of *Biochemistry and Pharmacology* Dr. Dale and Dr. Lovatt Evans have completed their work on the influence of carbon dioxide upon the maintenance of normal blood circulation, and have shown that carbonic acid exerts a specific action on the tone of the vasomotor centres. Dr. Burn's work on the relation of the sweating produced by the drug pilocarpine to the integrity of the nerve supply of the sweat glands has shown that the diminution or suppression of the sweating response, which attends the degeneration of the sensory nerve fibres to the skin area in question, is the result of defective blood circulation, caused by the loss of sensory fibres, a conclusion which raises issues of great importance concerning the so-called "trophic" or nutritive influence of sensory nerves. Dr. Dudley's work, designed to isolate the active principles of the pituitary gland in pure form, has yielded valuable information about the properties of this hormone, but has led to the conclusion that the active principles cannot be directly isolated and identified in a pure form by the methods at present available. Dr. King has completed a study of stereo-isomerism in the cinchona alkaloids, and has been engaged in investigating the active alkaloid of poisonous toadstools.

The staff of the *Experimental Pathology, Bacteriology, and Protistology* Department has been increased by the appointments of Dr. P. P. Laidlaw and Dr. W. J. Purdy. Dr. Douglas, the director of the department, has invented a transparent medium for the growth of *B. diphtheriae* on which the colonies of this organism have a distinctive appearance, whereas other bacteria are inhibited. In conjunction with Mr. Barnard he has carried out some experiments which show that overdoses of light rays from a mercury-vapour lamp tend to allow the tissues of resistant animals to be invaded by bacteria. Other experimental work by Dr. Douglas appears to make it certain that a temperature of 65°C. for thirty minutes will kill the tubercle bacilli in naturally infected cow's milk.

Dr. Gye and Dr. Purdy have been studying the poisonous properties of colloidal silica, and Dr. E. H. Kettle of St. Mary's Hospital has been working with Dr. Gye on the effects of silica dust upon the tissues, with special regard to the problems of industrial tuberculosis. These researches have shown that the lesions caused by the silica provide a nidus in which the tubercle bacilli, protected from the bactericidal defences possessed by the normal tissues, can multiply and so initiate

progressive damage. Dr. Laidlaw has been studying the factors which favour the growth of pathogenic bacteria, with special reference to the stimulating constituent present in meat extract, which is believed by some to be allied to the vitamins.

Dr. Colebrook, whilst at the Institute, carried out some experimental work for the Committee on the Causes of Dental Disease, being a study of the artificial erosion of teeth, of the types of acidophile bacilli occurring in the mouth, and the micro-organisms actually found in carious teeth. Dr. Tytler completed some investigations of the conditions favourable to the growth of some haemolytic strains of streptococcus obtained from scarlet fever cases, and studied the stimulating effect of blood serum in increasing the rate of growth and final bacterial concentration, and found that solutions of either fresh or crystallized haemoglobin had an effect on growth more powerful than that of serum. Mr. Dobell, in the Department of Protistology, has been preparing for publication an extensive study of the coccidia, and has also been working at the theory and practice of staining spirochaetes and other micro-organisms with silver salts.

In the Department of *Applied Physiology* Dr. Hill and Dr. Campbell have been working at various problems of body heat and metabolism. They noted when observing the rates of internal chemical exchanges in children crippled by surgical tuberculosis and lying fixed in splints in bed at the Lord Mayor Treloar Hospital, Alton, that the beneficial exposure of the children, more or less nude, to the open air in summer increased these exchanges in metabolism on an average to about 40 per cent. above the standard basal figures for closed chambers. Working at Montana, Switzerland, Dr. Hill studied the results of exposure to the alpine open air under a variety of conditions.

At the Institute, Hampstead, a wind tunnel and revolving platform have been constructed by means of which Dr. Hill and Dr. Campbell have been able to determine the amount of cooling necessary for comfort during various degrees of muscular work; the frequency of the heart beat was much less when the body was adequately cooled. Dr. Campbell and Mr. Webster studied the metabolic changes taking place in individuals working at night and sleeping during the day and compared these with the normal routine. Air injected into the pleural cavity (as in the treatment of consumption by the production of artificial pneumothorax) was found by Dr. Hill and Dr. Campbell to alter in its composition, and the partial pressures of the gases in this air appeared to approximate finally to those in the tissues and venous blood and not to those in the alveolar air of the lungs. In the Department of *Applied Optics* Mr. J. E. Barnard has carried out some valuable work on microscope technique and has commenced an investigation of the structure of bacteria.

In the Department of *Statistics* Dr. Brownlee has been engaged in preparing an account of the data necessary for the statistical study of immunity and in investigating the relation of scarlet fever to rainfall. Dr. Young has worked upon the data of the statistics of epidemic infantile diarrhoea and extended the investigation to several towns in the provinces and abroad. Mr. Russell has been studying the relationship between weather and disease, and the Registrar-General's statistics of the incidence of cancer in different trades have recently been placed at the disposal of the Council and have been extracted by the clerical staff of the Statistical Department.

Many additions have been made to the Library during the year and the Council again draws attention to the fact that approved persons interested in medical research are allowed free use of the library by arrangement with the librarian. Eight numbers of the Special Report Series (Nos. 60-67) have been published during the year and three others are in the press, while two (Nos. 19 and 38) are being completely revised, brought up to date, and reissued.

#### EXPERIMENTAL MEDICINE AND THE RESEARCH WORK OF CLINICAL UNITS.

At *University College Hospital*, London, Sir Thomas Lewis and his co-workers have been studying the effects of certain drugs on auricular fibrillation, particularly with a view to ascertaining if the actions of these drugs can be explained on the basis of the theory that fibrillation is due to a "circus" movement in the auricle. In searching for a drug which would produce a notable prolongation of the refractory period of the auricular muscle, atropine was first examined, but it was found that the customary clinical doses are insufficient to produce a maximal heart reaction, but that when adequate

larger doses are given a very definite effect is produced on the fibrillating auricle. When the discovery of von Frey became known in this country attention was turned at once to the study of the alkaloid quinine, and von Frey's statements were confirmed. Like atropine, it was found that quinine lengthens the refractory period, and it has this action in conspicuous degree; given in therapeutic doses its action in this respect far surpasses that known in the case of any other drug. Another notable effect of quinine was discovered to be its paralytic effect on the vagus nerves due to an action on the ganglia of the vagus, and not upon the vagal endings. Clinical observations have been undertaken to ascertain the most suitable methods of administering quinine, its proper dose and rate of absorption, and allied questions.

In the medical unit of the hospital Dr. J. W. McNee has continued his work on diseases of the liver and on the metabolism of cholesterol.

At the *London Hospital* Dr. A. W. M. Ellis has completed some investigations on the subject of "bacteriophage" phenomena and Dr. J. R. Marrack has continued research work on nephritis.

At *St. Thomas's Hospital* the chief research undertaken during the last year was an investigation into the value of renal tests in genito-urinary surgery, and it has been shown that many of the dangers associated with this branch of surgery may be avoided or overcome by a judicious investigation beforehand of the renal efficiency.

At the *Royal Infirmary, Edinburgh*, Dr. Davies has studied the respiratory function in disease and has made a series of determinations of the basal metabolism in various pathological states. Mr. Harrington has investigated the occurrence and distribution of histamine in the human bowel.

Research work in professional practice has been encouraged and assisted in many places, notably at Norwich, Hull, Glasgow, Newcastle, and in London. Grants have also been made to the *St. Andrews Institute of Clinical Research*, where, under the direction of Sir James Mackenzie, important schemes of research into the early stages of disease are being pursued.

#### DETERMINATION OF BIOLOGICAL STANDARDS AND THE METHODS OF BIOLOGICAL ASSAY AND MEASUREMENT.

A standard test for arsenobenzol compounds has been evolved by estimating the curative effect of these compounds on mice infected with *Trypanosoma equiperdum*, and manufacturers have been enabled to modify their processes so as to produce neo-salvarsans which satisfy the tests now imposed.

The standardization of pituitary extract has been made possible by the work of Dr. Dale and Dr. Burn, who have indicated a method of comparison of a trustworthy standard of reference and of a method of comparison which, if faithfully observed, would suffice to eliminate any significant fluctuations in the activity of this extremely valuable but dangerously powerful remedy.

Dr. P. Hartley is continuing the work on the standardization of antidipteria serum, which was commenced by Dr. Colebrook.

The *National Collection of Type Cultures* has received during the year many valuable additions to the collection. Over 300 fresh types were received into the collection and over 2,500 cultures were distributed.

The production of standard cultures and serums for use in diagnosis of enteric and dysenteric infections has been continued at the Standards Laboratory at Oxford, and during the course of twelve months 297 orders for cultures and 116 orders for serums have been executed.

*The Sero-diagnosis of Syphilis.*—One thousand samples of blood from syphilitic patients and from controls have been submitted to examination by the sigma reaction of Dreyer and Ward and the orthodox Wassermann reaction, and the results of this trial will shortly be ready for publication. Work is being carried out with the object of producing standard antidyenteric, antipneumococci, and antimeningococci serums.

*Anthropometric Methods and Standards of Medical Measurements.*—The main object of this investigation has been the correlation of Professor Dreyer's "vital capacity" test for physical fitness with other measurements, and this work has been continued by Dr. F. G. Hobson at the University of Oxford. Dr. G. H. Hunt and Professor M. S. Pembrey have extended their observations upon the influence of muscular work upon the heart, especially in relation to the factors that influence the pulse ratio.

#### RESEARCH IN SPECIFIC SUBJECTS.

##### *Problems of Child Life.*

Under the heading of *Pre-natal Studies* the factors contributing to dead births and premature births have been examined by a large number of workers, and the combined results have been placed in the hands of a special sub-committee consisting of Dr. J. W. Ballantyne, Dr. J. S. Fairbairn, and Mr. Eardley Holland, from whom a report is shortly expected for publication by the Council. The toxæmias of pregnancy have been investigated by Dr. O. L. V. de Wesselow, who has shown that examination of the kidney functions appears to give information as to the course of the disease, which is of value to the clinician in determining whether induction of labour is necessary or desirable. Metabolism and general physiology in pregnancy and the lying-in period have been studied by a group of workers at the Royal Free Hospital and School of Medicine for Women. An inquiry into the influence of maternal nutrition upon the infant has been commenced at St. Thomas's Hospital under the direction of Dr. J. S. Fairbairn.

Under the heading of *Post-natal Studies* there is described an investigation carried out under the auspices of the Scottish Child Life Committee into the influence of various factors on nutrition and growth, both by the collection of records from child welfare centres and by the home visitations of special workers in the service of the Council. Many of the records received were unsatisfactory, but after a thorough weeding out of imperfect documents over 3,000 schedules, having over 5,000 height and weight records, have already been completed with sufficient accuracy. An analysis of these figures shows that no correlation is manifest between the nutrition of the child under 1 year and the size of the family, position of the child in the family, or number of persons per room. The suggestion is that irrespective of these conditions, even if unfavourable, the infant may still start life unhindered. "On the other hand," to quote the words of the report, "there appears to be an indication of a direct correlation between the condition of the child and the health of the mother during pregnancy. As regards the influence of feeding the information obtainable is not sufficient to allow a valid estimate to be made of the effect of this important factor because the data are not quantitative. All that could be done was to attempt to determine whether any differences in growth and nutrition could be found as between infants breast-fed for three months and over and those not breast-fed at all, or breast-fed only for a shorter period than three months. No correlation, however, could be established here."

The special visitors in the service of the Council obtained records of over 500 families visited in Glasgow and 220 in Dundee, and with the co-operation of Dr. Weir and other members of the anatomical staff of the University of Glasgow obtained records of about 4,000 school children. In order to express numerically the state of growth and nutrition it was decided to take height in inches as the measure of growth and height for age as the measure of nutrition. The results of this extensive inquiry may be briefly summarized as follows. Over 91 per cent. of the children were of the brown-haired or completely mixed type, and no notable difference in stature subsisted between the fair-haired and dark-haired groups. It has been established that the size of the offspring is related to the size of the parents, and the high proportion of stunted adults in Dundee gave an opportunity of investigating this. There seemed to be a direct correlation between the size of the family, the family income, and the air space per person, and the nutrition of the child.

Work on the metabolism of infants has been carried out by Dr. G. B. Fleming and Dr. J. A. Gardner.

##### *Rickets.*

Further experiments have been carried out by Professor Noël Paton and his associates to test the possibility that rickets may be an infectious disease, and to elucidate the modes in which dietetic modifications may cause or prevent the disorder. At the Royal Hospital for Sick Children, Glasgow, Dr. Galbraith has studied the results of different therapeutic measures in 47 cases of rickets, and an account of this work will be published in due course. Professor Mellanby, who, thanks to the co-operation of the University of Sheffield, now possesses exceptional facilities for studying this disease, has been more particularly concerned with the relationship of the antirachitic food factor to calcium and

phosphorus in the diet, with the relative rickets-producing effects of different cereals, and with the influence upon rickets of thyroid gland administered by the mouth.

#### *Accessory Food Factors (Vitamins).*

Dr. J. C. Drummond and Dr. S. S. Zilva have carried out further work on the nature of the substances giving its valuable therapeutic qualities to cod-liver oil, and endeavoured to trace the origin of the so-called vitamin A, which is held to be the active substance responsible for the beneficial effects obtained in the use of the oil. It has been shown that simple marine diatoms growing in an artificial inorganic medium can produce relatively large amounts of the vitamin. But the diatoms do not form the direct food supply of the species from which the liver oils are usually derived, and there are several stages through which the vitamin appears to be transferred. The minute animal organisms near the surface of the sea feed directly on the microscopic plants, and these in turn constitute the food supply of numerous small kinds of fish or the young of larger kinds. The fish from which the medicinal oils are derived feed chiefly on the smaller fish and store up the vitamin transferred in this manner. Dr. Zilva and Dr. Drummond have shown that there is very little loss of vitamin during the steaming processes, which are now generally employed by manufacturers, but there are wide variations in the vitamin values of different samples of cod or other fish liver oils, which may be due to the variations in the food supply of the fish, or to the seasonal variation in their physiological condition. The vitamin values for cow's milk and butter are known to be higher during grass feeding in summer than during winter feeding on roots, hay, and "concentrates"; by giving the cows cod-liver oil as a supplement to a diet of hay, roots, and cake mixture evidence of increased nutritive value of the butter was obtained.

Professor Korenchewsky, working at the Lister Institute, has made it clear from his extensive chemical and histological observations that vitamin A, or some other factor as yet not differentiated from it and of similar distribution in animal fats, exerts a controlling influence in the deposition of calcium in the skeleton. A deficiency of calcium and phosphates in the diet appears to play a contributory part. Dr. Goldblatt's experiments show a close correspondence between the amount of vitamin A in the diet and the calcium content of the skeleton.

An investigation of the values of different dietaries during the school age of life has been begun by Dr. H. Corry Mann. At a model village outside London where about 600 boys of the industrial class are housed in separate homes, each containing some thirty boys, three houses have been assigned for the work, and these are occupied by batches of boys between 7 and 12 years, and whose weights lie between 45 and 70 lb. Repeated clinical examinations are made, and notes are taken of general development at regular intervals. During a preliminary period of four months the progress of all the boys was watched while they were consuming the basic diet of the village. By means of food analyses an estimate has been obtained both of quality and caloric value of the individual rations eaten. After the four months on the basic diet a change was made, and two of the homes have since received additional items of food, the third home remaining on the basic diet as a control group of thirty boys. In one of the homes the additional item is fresh milk; and it is proposed to continue the investigation for at least two years, the progress of the boys being noted.

The work on deficiency diseases in Vienna has been continued during the past year with the joint support of the Medical Research Council and the Lister Institute by a staff of workers under the direction of Dr. Harriette Chick, the main object being to observe the part played by diet in the prophylaxis of rickets in young infants. The observations have been made upon nearly 100 young infants, who were placed in two groups upon two contrasted diets but under identical conditions of general management and hygiene. Diet I was high in calories, high in carbohydrates, low in fat, and low in vitamin A. Diet II was lower in total calories, lower in carbohydrate, richer in fat, and, as it contained a daily ration of cod-liver oil, much richer in vitamin A. The results of this observation on prophylaxis showed—

"1. That slight but definite rickets was developed with great regularity during winter upon Diet I, but not upon Diet II.

"2. That it was not developed in summer upon either diet.

"3. That the age of greatest susceptibility to the onset of rickets is during the first half-year of life."

A comparison was made of the effects of treatment of rickets with cod-liver oil, radiation from the mercury-vapour quartz lamp, and sunshine out of doors. The results as observed by systematic x-ray photography showed that deposition of calcium occurred consistently in the epiphyses of children under any of these three forms of treatment, while negative results were obtained in the control children. These results lead to the conclusion that quality of diet, especially absence of antirachitic element, is probably the most important factor in the causation of rickets in winter, and that sunshine may be the chief preventive factor in summer.

#### *Human Nutrition.*

Studies in human nutrition have been carried on in the physiology department of King's College for Women, under the direction of Professor V. H. Mottram. Miss Hartwell has shown that a diet rich in protein given to a nursing rat injures the health of the litter. These high protein diets are unsuitable only during lactation, and appear to be beneficial for growth, fertilization, or reproduction. The addition of milk in large quantities to the diet protects the offspring from the special danger from high protein diet during lactation. By a process of elimination this protective substance was traced to vitamin B. Miss Clifford's studies on the preservation of meat by various methods of cold storage have been chiefly concerned with the distribution of carnosine in the animal kingdom.

#### *Causes of Dental Caries.*

The Committee on the Causes of Dental Disease, under the chairmanship of Professor W. H. Halliburton, has initiated several investigations which are being carried out in different parts of the country.

#### *Disorders of the Cardio-vascular System.*

In addition to the work of Sir Thomas Lewis and his colleagues already referred to, many other researches have been assisted by grants from the Council, as, for example, the investigations on disordered action of the heart which Dr. H. J. Starling has been conducting at Norwich.

#### *Exophthalmic Goitre.*

At Sheffield Professor Mellanby has been making a closer study of the dietetic factors causing abnormal developments in the thyroid gland, and grants have also been made to Dr. G. S. Williamson at the Royal Free Hospital, London, and Dr. G. K. Stone at St. Bartholomew's.

#### *Disorders of the Respiratory System.*

Special attention has been paid to the clinical uses of oxygen by workers at Guy's Hospital, and Professor J. C. Meakins has continued his tests of the utility of the more portable forms of apparatus devised for the administration of oxygen in disease. Medical problems of high flying have been studied by Major H. F. Pierce, working at the University of Oxford.

#### *Disorders of the Excretory System.*

Work on experimental nephritis carried out by Professor J. Shaw Dunn at Manchester and Dr. A. S. Strachan at Glasgow has been assisted by grants from the Council.

#### *Disorders of the Nervous System.*

General neurological studies have been undertaken by Professor T. Graham Brown, Dr. Iry McKenzie, and Dr. J. P. Hettwer, and the special Committee on Nerve Injuries has been preparing data for a report on injuries of the spinal cord. A group of workers at the University and Western Infirmary, Glasgow, have continued their researches on that common and distressing form of progressive paralysis, disseminated sclerosis, and the pathological changes which take place in neuro-syphilis. Dr. C. De Fano has continued

Perdrau that the vesicular fluid from certain forms of skin affection (for example, herpes) contains a virus capable of producing a disease in animals which is transmissible from one animal to another and produces fatal lesions, in many ways similar to those of encephalitis lethargica. Minute bodies have been found in the vesicular fluid of herpes and in the brain tissue of infected animals, and it is possible that the smallest of these structures may represent the virus itself.

*Mental Disorders.*

At the University of Cambridge Miss L. G. Fildes has continued to receive a grant for whole-time research work in the causes of mental defect in children with the object of discovering what specific psychological characters exist which mark off a mentally defective from a mentally normal individual. Grants have been made to numerous other workers who are studying problems connected with mental disorders.

*Tuberculosis.*

From a study of another series of cases, 132 in number, of bone and joint tuberculosis, Dr. A. Stanley Griffiths has been able to show that the infection has been of bovine origin in rather more than 20 per cent. of the cases under 16 years of age, and 6.5 per cent. of the cases over 16. Dr. Inman has been working on the morphology and agglutinability of the tubercle bacillus, and Dr. Coulthard has completed an investigation into the complement fixation reaction in tuberculous cases.

The opsonic index in tuberculosis has been made the subject of a special study by Miss C. M. Acland, working with Colonel S. L. Cummins at Cardiff; and the work which Dr. Charles Miller and Dr. H. M. Turnbull have been carrying out at the London Hospital on the primary sites of infection in cases of children under 10 years of age is being continued. Dr. L. S. T. Burrell and Dr. A. S. MacNalty have prepared a report on the value of artificial pneumothorax as a method of treatment in pulmonary tuberculosis, with a discussion of the attendant dangers and difficulties, and of the groups of patients for which the method is suitable. Professor G. Dreyer and Dr. H. K. Ward are continuing their researches on the standardization of tuberculin. The importance of this work is made manifest by the report of the Tuberculin Subcommittee, which came to the conclusion "that until an accurate method of standardizing tuberculin is obtained, the administration of tuberculin can only be carried out empirically as a therapeutic measure, and the results in human tuberculosis cannot be evaluated or scientifically controlled." The greater part of the Tuberculin Subcommittee's work has been given to an investigation into the efficacy of the various tuberculin tests in cattle, and a full report on these inquiries will be presented at an early date. Grants have been made by the Council to research workers in different parts of the country who have been studying chemotherapy in tuberculosis, and records of the after-histories of sanatorium patients have been collected from special sanatoriums.

*Influenza.*

The Council has published the work of Professor James McIntosh on the etiology of influenza<sup>1</sup>; it has furnished a grant to Dr. P. Fildes for his work on the conditions of growth of *B. influenzae*; and Dr. Gordon's work on the presence of a filter-passing organism in the early stages of influenza<sup>2</sup> has been undertaken on behalf of the Council.

*Studies of the Streptococcus and Pneumococcus Group.*

Dr. Gordon has continued his study of the characters and clinical significance of pathogenic streptococci, chiefly by serological methods, chief attention having been given during the past year to non-haemolytic strains. In contrast to the striking uniformity which had been found to exist amongst the haemolytic streptococci when studied by serological methods, it has now been found that seventeen specimens of non-haemolytic *S. salivarius* recovered from endocarditis during the past year are separable into at least fourteen distinct serological types, and of three specimens of *S. faecalis* from similar cases all were found to be distinct serologically from one another. Dr. G. K. Stone has shown that while the complement fixation test is far more delicate than the agglutination test for identifying streptococcal infections, and has certain other advantages over it, it is less specific in the sense that infections by the three types—*S. pyogenes*, *S. salivarius*, and *S. faecalis*—are not differentiated so sharply or completely by complement fixation as by agglutination. Dr. R. R. Armstrong has been studying the serological types of pneumococci and the relative prevalence of the various types of infections in acute pneumococcal diseases in this country. Dr. J. F. Gaskell has been studying the modes in which the lungs offer resistance to infection, and concludes that the character of the lesion produced under different conditions of infection does not depend on the type of the infecting organism but upon its virulence.

<sup>1</sup> See BRITISH MEDICAL JOURNAL, July 22nd, 1922, p. 137, and August 19th, p. 303.

<sup>2</sup> See BRITISH MEDICAL JOURNAL, August 19th, 1922, p. 293.

*Arthritis.*

Dr. T. S. P. Strangeways and Major Horne, I.M.S., have received assistance in their work on rheumatoid arthritis. Mr. A. G. T. Fisher's work has shown that the earlier changes in the joints are primarily inflammatory rather than degenerative, and evidence has been added to that already pointing to the important effects of toxic substances derived from chronic infective foci in the alimentary tract and elsewhere.

*Malignant Disease.*

Grants have been made to Dr. James Young, for his work on the causation of cancer, and to Mr. A. N. Currie, who has been working at the significance of fat and lipochromes in the etiology of cancer.

*Radiology and Radiotherapy.*

The radium bromide held by the Council for research purposes has been allocated to different institutions, at each of which special investigations have been commenced in the treatment of disease by radiation.

*The Biological Actions of Light.*

Plans have been made for investigation of the specific effects of light and of its different constituent rays on the body fluids and tissues and their simpler components, and on bacteria and protozoa both within the body and outside it. Many of these investigations have already commenced at different centres.

*General Biochemical Researches.*

Under this head are included researches in bacterial chemistry, the oxidation in the tissues, responses to meals, metabolism in diabetes, efficiency of hepatic function, distribution of glycogen and other carbohydrates in the body, properties of haemoglobin, action of diuretics, and the uses of pituitary extract in childbirth. Researches in all these subjects, carried out by different investigators, have been assisted by grants from the Council.

*General Physiological and Pathological Researches.*

An account is given in the report of a large number of investigations in general physiological and pathological problems the expenses of which have been defrayed either in part or in toto by the funds of the Council.

*Experimental Epidemiology.*

The experiments which Dr. W. W. C. Topley and his co-workers have carried out on the problem of the spread of epidemics amongst mice have been assisted financially. His important observations on the course of events during the pre-epidemic phase of the spread of infection and on the effects of dispersal of the population have already been published.

*Meta-zoon Parasitology.*

The report mentions researches on "the structure and infections of lice and ticks" and "worm infections," towards which the Council has supplied grants.

*INDUSTRIAL MEDICINE AND INDUSTRIAL FATIGUE.*

The Council has provided expenses for researches on dust inhalation and pulmonary disease, miners' nystagmus, miners' "beat knee," "beat hand," and "beat elbow," ankylostomiasis in Cornish miners, and the incidence of occupational diseases. The unprecedented trade depression throughout the year greatly affected the work of the Industrial Fatigue Research Board, and has prevented the full development of the schemes foreshadowed in a previous annual report. On the other hand, advantage has been taken of this abnormal period to gain knowledge of the effects of short time and of the changes in the usual incentives in industrial work. Mention is made in the report of various investigations completed during the year or now in progress.

*CONCLUSION.*

In concluding this report the Council refers with gratitude to the generous gift of the Board of the Rockefeller Foundation of New York of 2,000,000 dollars to the Government for the purchase of a site and the erection of a building for a great school of hygiene in association with the University of London. Reference is made also to the important endowments to medicine and its allied sciences which have come recently from within our own country, and in particular to the gift of £100,000 made by the trustees of Sir William Dunn's residuary estate to the University of Oxford for the

building and maintenance of a new school of pathology; the trustees have also undertaken to provide funds for converting the present pathological buildings into an adequate school of pharmacology. Finally, mention is made of the important financial help recently given by the same trustees to the clinical units in St. Bartholomew's Hospital, St. Thomas's Hospital, and the London Hospital, for the construction and equipment of either new or improved laboratories.

Other important benefactions to medical science made in the past year to which the report refers include the sum of over £80,000 under the will of the late Miss Foulerton for the endowment of research work, at the discretion of the Royal Society, the gift of £20,000 by Lord Atholstan to the Imperial Cancer Research Fund, and £10,000 by Sir William Veno to the Cancer Research Department of the Middlesex Hospital. One gift which the Council considers to have special significance is that of the Panel Committee of Sheffield, which has contributed £1,000 to the University of Sheffield towards the provision and equipment of the Field Laboratories which have been erected by the university close to the city.

## Nova et Vetera.

### MEDICINE IN CHINA.

THE Chinese trace the beginnings of their art of healing to the legendary Yellow Emperor, who is said to have ruled about the middle of the third millennium before Christ.

#### *Legendary Origins.*

The Yellow Emperor was aided in his administration by a group of supermen, whose names are still current in popular tradition as pioneers of most of the sciences, arts, and crafts since practised by the race. One of his beneficent acts was to take counsel how to prolong the span of human life, since he was grieved at the many bodily ills afflicting his subjects. It is narrated that with the help of several of his physicians he succeeded in studying problems of public health to such good effect that the longevity of the people was substantially increased. At the present day there exist several medical treatises attributed to the Yellow Emperor. This association with his name can hardly be regarded as implying more than extreme antiquity for the notions recorded, yet there seems reason for believing that the oldest of the books was actually compiled several centuries before our era, and that it then provided a summary of medical knowledge handed down from the remotest past.

Several centuries earlier than the famous Alexandrian school of anatomy under the Ptolemys, a Chinese physician, named Pien Ch'iao, is reputed to have performed human dissections, and understood the function of blood vessels. His name is still connected with the elaborate pseudo-science of the pulse professed by Chinese leeches, and it may safely be concluded that his acquaintance with the structure of the body was very slight. Hua T'o, another doctor living some eight centuries later, has been called by Western writers the Asklepios of his race. This title, however, would be more appropriate to the physician hero-god Ch'i Po, who was the chief adviser of the Yellow Emperor in his hygienic reforms, while Hua T'o might suitably be termed the Chinese Hippocrates. Hua T'o is said to have used an anaesthetic agent for his surgical operations. The drugs employed cannot be identified with certainty; probably they were compounded of aconite, henbane, and datura. Hua T'o is renowned as the first to operate successfully on cataract. He ended his days A.D. 220 in prison, where he had been cast by the most powerful man in the empire, who had consulted him for violent headaches, and was advised to have his skull opened under an anaesthetic. The patient suspected in this the treacherous design of some enemy, and indignantly refused. He died the same year as the doctor from what appears to have been a cerebral tumour.

#### *Taoism and Alchemy.*

The foregoing scraps of legend and history are sufficient to suggest that the ancient Chinese were not far behind their Mediterranean contemporaries in medical knowledge. Questions about possible borrowing by the East from the West in those remote times await fuller investigation. On the other hand, our present knowledge makes it permissible to formulate a plausible enough theory showing China the mother of at least one of our own sciences. The names mentioned above are those of reputed exponents of a cult

embracing many activities besides the arts of healing and physical development. The cult of Tao appears early in the records of authentic history as concerned with a search for the Elixir of Life and the Philosopher's Stone. There are accounts of certain feudal princes dispatching expeditions under the leadership of its sectaries to bring back the magic agencies they believed were to be found in some mid-ocean paradise—the *Insula Fortunatae* of the Far East. In the fourth century B.C. the first band of venturers sailed from the coast of China, and it was followed by others. Emperors, in feverish pursuit of immortality, lavished riches and honours on Taoist charlatans. One in 133 B.C. gave his imperial sanction to alchemy, and we may infer from the passage recording the event that the art was then no new one. Taoist alchemists increased exceedingly, and for many centuries numbers of recluses carried out mysterious researches with the crucible in their mountain hermitages, or roamed the countryside plucking herbs from which to brew death-defying potions. A most voluminous literature is devoted to stories of those happy ones who thereby escaped the fate of ordinary mortals. Nevertheless, the truth-loving compilers of dynastic annals are fain to chronicle the demise of many as the result of drinking Elixirs of Life, and among the number are several emperors. Yet there is reason to believe that not a few Taoists trod a middle path between these two extremes, and thus acquired much knowledge of plants and minerals which was turned to useful purpose by the race.

Very similar on our side of the world is the tale of the pursuit of immortality and transmutation of metals. Striking resemblances are to be found between the writings of Western and Chinese alchemists—resemblances that extend even to the actual jargon that cloaks their mysteries. But the two schools are separated by differences of time, and to the Chinese the priority is undoubtedly due. The theory hinted at earlier in this article is that much of Western alchemy, the forerunner of chemistry, was derived from China, chiefly through Mohammedan intermediaries. Evidence of communication between the Chinese, Persians, Arabs, and even Greeks in Constantinople is ample enough to prove that opportunities were not lacking for the passage of the mysteries westward.

#### *Western Medicine in China.*

But whatever indebtedness there may have been on our side, the balance is surely now being adjusted. Western medical science has been carried to China both by men of our own race and by Chinese trained in our schools. Dr. Peter Parker opened an ophthalmic hospital in Canton in 1835, and not long afterwards a native, holding Scottish qualifications, started to practise among his countrymen in the south. Since then practitioners and teachers of many nationalities in increasing numbers have offered the benefits of Western learning to the Chinese. One of the most eminent medical men in the Far East is Dr. Wu Lien-teh, known to many in this country under the name of G. L. Tuck. After a distinguished academic career at Cambridge, Paris, and London, Dr. Wu returned to his native land and became a pioneer of public health administration. The immensity of the task confronting him can hardly be appreciated by those unfamiliar with the vastness of China and the complacency with which the greater part of its millions accept conditions little advanced during the sixteen centuries since the physician Hua T'o died in his dungeon.

#### *Plague Prevention To-day.*

The deadly outbreak of plague in Manchuria, 1910–11, profoundly stirred the apprehensions of Chinese and foreigners alike, and paved the way for the establishment of the North Manchurian Plague Prevention Service with headquarters in Harbin. Dr. Wu practically created this efficient organization, and a recent report, now before us, commemorates the tenth year of its existence under his able directorship.<sup>1</sup> This stout and well printed volume of 354 pages is far from being a mere matter-of-fact record of the doings during the last four years of the Plague Prevention Service formally instituted in October, 1912. It contains many articles on divers subjects of vital interest respecting the progress of Western medicine in China. For instance, there is an important memorandum outlining a suggested scheme of medical education, and there is a survey of the advances made since the establishment of the Republic in 1911. It may be noted,

<sup>1</sup> North Manchurian Plague Prevention Service Reports, 1915–1922. Edited by Wu Lien-teh, M.A., M.D. Cantab. Tientsin, 1922. (Pp. 354; 37 illustrations, 1 map, and 2 charts).

by the way, that this mentions the epoch-making event of a presidential mandate authorizing human dissection. Some of these articles have appeared before in various journals, but a great part of the clinical matter is published here for the first time. The second pneumonic plague epidemic in Manchuria, 1920-21, is admirably recorded, and of great interest, too, is an account of the cholera epidemic of 1919. A vast deal of laboratory research, including experiments on tarabagans, occupies an important section of the book. Further, the report is enlivened by numerous excellent illustrations not concerned solely with the manifestations of disease. All the contents are contributed by members of the Prevention Service staff, and we note that a large share comes from the pen of the editor himself.

Perusal of this book impresses one with the fact that the Plague Prevention Service has far more than justified its existence. The work it has achieved at the comparatively small annual cost of 60,000 taels (90,000 dols.) offers an object lesson of economical administration which might well be studied in some Western countries. It was Dr. Wu's earnest hope to expand this small but efficient service into a national Department of Public Health. The times have been against him, but if he achieve his ambition assuredly he will be regarded as no less a benefactor to his race than some of the illustrious personages we have named.

W. P. Y.

## WINTERING ABROAD.

### ITALY.

#### THE LIGURIAN RIVIERA.

THE frontier between France and Italy on the Mediterranean coast is a diplomatic line not marked by any prominent natural feature. What was said in general terms about the French Riviera in the article published in our issue of October 28th, 1922 (p. 815), applies likewise, in the same general way, to the adjacent places in Italy, though here also the particular character of the climate may be influenced by local topographical conditions. About thirty miles farther on, however, the coast takes a north-easterly trend, so that the places on this part of it, speaking generally, look south-east; behind all of them are hills near or not far back. These two facts may serve to account for the claim that the mistral is little felt, or altogether unknown, in this part of the Riviera, for the mistral is a north-westerly wind. The whole coast from the French frontier to Spezia is spoken of as the Ligurian Riviera, but it is divided into two at the head of the Gulf of Genoa, where the coast trends south-west, so that its general aspect is south-westerly. The part between the frontier and Genoa is known as the Western Italian Riviera (Riviera di Ponente), and the rest, to Spezia, as the Eastern Italian Riviera (Riviera di Levante). These two stretches of coast, therefore, look at each other across the Gulf of Genoa.

#### Riviera di Ponente.

It is claimed for the Riviera di Ponente that it has a dry and stimulating air, with abundant sunshine, and few wet days. The rainfall, though it does not differ greatly in quantity from that at the southern English winter resorts, occurs on many fewer days—five instead of fifteen. It is, of course, heavy while it lasts, but fogs and mists are infrequent. The disagreeable wind is from the east, but it is often possible to find a resort sheltered from that quarter. It is said that the drop in temperature at sunset is less than on the French Riviera. Great stress is laid on the dryness of the atmosphere, which is favourable to many conditions, including chronic bronchitis, but is often found not to suit persons of nervous temperament, who may find it too stimulating.

The places most frequented by visitors from this country are, taking them in order from west to east, Bordighera, San Remo, and Alassio. The first-named is a very pleasant place of residence; the old town clusters round a hill, the new runs westward, and consists mainly of a single thoroughfare parallel with, and close to, the shore. The place is well protected on the north and east, and its gardens are famous. It has many hotels, two casinos, an English club, a tennis club, and the ~~country~~ <sup>country</sup> affords many beautiful walks and ~~is~~ <sup>is</sup> modes in which the oldest and ~~most~~ <sup>most</sup> interesting section, and concludes that the Riviera di ~~Ponente~~ <sup>Ponente</sup> is the best resort of the infecting ~~area~~ <sup>area</sup> in two bays ~~and~~ <sup>and</sup> extends.

The eastern bay is the more sheltered, but both enjoy an equally large measure of sunshine. San Remo also has many hotels, an English club, and an English nursing institute. Its chief industry is the export of flowers; especially carnations, which are largely cultivated on the terraced slopes; a few miles away, at Taggia, there are violet farms. At Alassio the old town stretches along the shore, and visitors stay in villas or hotels on the slopes behind. It is considered to be one of the warmest resorts on this coast, and is a good centre for excursions along the seashore or into the hills at the back.

There are many other smaller resorts on the Riviera di Ponente. Ospedaletto, which lies between San Remo and Bordighera, advances the claim that it is the most sheltered spot on this Riviera and has the most equable climate. It is protected on the east, north, and west by hills. The hotels and villas are for the most part set a little back from the fishing village itself, on wooded slopes with many pine trees. The cultivation of flowers is the chief local industry. There are several good hotels and a casino. Diano Marina, between San Remo and Alassio, and Varazze, a good deal farther along the coast, are smaller places, but are well situated and have adequate accommodation. Lastly comes Pegli, a small town set under hills covered with olive trees, and woods of chestnuts and pine. It is a picturesque place, now almost a residential suburb of Genoa.

#### Riviera di Levante.

Passing to the Riviera di Levante the first resort is Nervi, about seven miles from Genoa. Here the mountains come down close to the sea, and the place is consequently very sheltered; it is therefore suited to those classes of invalids for whom a very mild winter climate is desired. It has several hotels, and is frequented chiefly by the sick rather than by the pleasure seeker. The gem of this part of the coast is the Portofino Peninsula. From the crest of the peninsula it is possible on a clear day to see across the bay, even to the headlands of the French coast, seaward to Corsica, southwards all along the coast to Spezia. To reach Portofino the visitor must leave the train at Santa Margherita, which is itself a good centre for walking excursions. Though it has the sun on it for a longer time it is not so well sheltered from the east as Rapallo, which is perhaps the best known resort on the Riviera di Levante. It has a casino and many hotels. Visitors are attracted especially by the picturesque coastline; to the east it rises in precipitous rocky cliffs; westward the coast is lower and is traversed by the road through Santa Margherita to Portofino. There are a number of small places beyond this before the naval port of Spezia is reached.

#### Journey: Cost.

The longer journey, with its increased cost, deters many British visitors from penetrating to the eastern part of the Ligurian Riviera. The cost of living in Italy, which was very low before the war, has increased very considerably since 1914; the increase is in fact even greater than in this country, but this is to some extent compensated by the present rate of exchange. Not a bad plan is to go first to one of the larger resorts and spend a week or ten days in looking about the neighbouring places. *En pension* terms for rooms, breakfast, lunch, and dinner, can usually be obtained at hotels for visits of not less than five days; but the actual rates of course vary according to the class of hotel selected. Visitors who know their way about will be able to find good accommodation at very moderate rates, when the exchange is considered, in the smaller hotels, and the cooking may be put down roughly as ranging from 60 to 40 lire a day. There is a tax on hotel bills varying from 1 to 12 per cent., according to the category of the hotel, but averaging perhaps 6 per cent. An addition of 10 per cent. is made to the account for service, and direct tipping is supposed to be eliminated. There is also a sojourn tax, similar to the "Kurtax" levied at German and Austrian resorts; it may be fixed on the basis of 10 per cent. of the price of the visitor's room, but in some places there is a charge of from 50 to 30 lire for the season.

With regard to the best routes to take to the selected resort information can be obtained from the Tourist Office of the Italian State Railways, 12, Waterloo Place, Regent Street, London, S.W.1, where advice will be given about the journey, as to the best way of transmitting funds to Italy, about the selection of hotels or pensions, and as to passports and visas.

## THE NAPLES RIVIERA AND SICILY.

A visit to the Naples Riviera involves a long railway journey, but the district, which includes all the resorts on the Bay of Naples, and the islands of Capri, Ischia, Procida, as well as Amalfi and Ravello, affords a considerable variety of climate, owing to the different situation and aspect of the various places. The climate of Naples itself is reputed to be dry, and the town is a good centre for excursions. The rainfall of Capri is low; the temperature is slightly higher than on the Ligurian Riviera, and the drop at sunset not marked. Sorrento, which has a fine casino and terrace looking over towards Naples and Vesuvius, is perched on rocky cliffs which rise to a height of about 300 feet. It faces north, and is therefore in midwinter rather cold for an invalid. Twenty miles away, on the Bay of Salerno, is Amalfi; it is reached from Sorrento by a road the beauty of which is far-famed. It faces due south, and the climate is described as bracing, with many bright clear days. Excursions may be made from it to Ravello, Salerno, and Paestum.

Sicily can be reached from Naples by a night journey, either by boat to Palermo (twelve hours), or by train to Messina, and then across the straits in half an hour. Palermo, the place most frequented, has an equable soothing climate, with a small range of temperature and little rain, except in December. There are good hotels at Palermo and also at Taormina, but full exploration of the island, with its many beauties and antiquities, should only be undertaken by robust persons willing to make the best of the local accommodation.

## MADEIRA.

Madeira is a place which had a great reputation as a winter resort in the mid-nineteenth century. Many consumptives went there only to die, and for this and other reasons its popularity waned; but it is now reviving. It can be reached by the boats of the Union Castle Line from Southampton, the average passage being three days and a half. The boats of the Yeoward Line and the Booth Line run regularly from Liverpool, and those of the Elder Dempster Line occasionally. The boats of the Booth and Elder Dempster Lines call at Lisbon and sometimes at Vigo. The island of Madeira lies in the Atlantic three or four hundred miles due west of Morocco. It is 32 miles long and 13 broad, and the interior is mountainous, rising to 6,000 feet. Funchal, the capital, lies on the south side of the island in a sheltered position, and is the place chiefly frequented by foreign visitors. We are informed by Dr. Geddes-Scott, who resides there, that the mean winter temperature is 62° F., and the diurnal variation averages 4° F.; the mean summer temperature is 77° F. The town slopes up gradually from sea-level to some 700 feet, but there are many villas (quintas) higher up. The average rainfall, the same informant tells us, is some 26 inches, falling mostly in November and December, and he lays stress on the absence of dust even in dry weather. In the spring the vegetation of Madeira is remarkable and the supply of fruit excellent nearly all the year round. There are several good hotels, and an international nursing home a little outside the town, overlooking the sea. Before making the journey a tuberculous patient should make sure of accommodation, as some of the hotels object to receiving visitors suffering from that disorder. With regard to the type of tuberculosis which does best in Madeira Dr. Geddes-Scott states that patients suffering from laryngeal tuberculosis often do remarkably well, as do cases of pulmonary disease with concomitant bronchial irritation, cough, and expectoration, even though hæmoptysis and high evening temperature be present. A patient with a hard dry cough and little sputum and not much elevation of temperature will probably do better elsewhere. Sufferers from chronic bronchitis can lead a healthy outdoor life, and asthmatics do well owing to the absence of dust. The water supply is now good, and the rate of exchange is favourable to the holder of English money.

THE *Archivos de medicina, cirugía y especialidades* of Madrid has offered a prize of 1,000 pesetas for the best unpublished work on natural science or medicine.

The Guild of SS. Luke, Cosmas, and Damian was established in 1900 to facilitate intercourse in the British Empire between Roman Catholic members of the medical profession and the clergy and others, for the study and discussion of medico-religious questions. The Guild has decided to issue a quarterly organ, *The Catholic Medical Guardian*, the first number of which will be published this month by Messrs. Barnes, Oates, and Washbourne, Ltd., at the price of 1s. 4d., post free.

## DANISH STUDIES OF THE INFLUENZA BACILLUS OF PFEIFFER.

INFLUENZA is so great a scourge, and its return is so assured, that all investigations tending to throw light upon its causation are worthy of attention. The recent discussion on the microbiology of influenza at the Annual Meeting of the British Medical Association at Glasgow<sup>1</sup> brought out the fact that notwithstanding the researches made during the pandemic of 1918, and smaller recurrences since that date, there is at present a lack of agreement concerning the primary infective agent of influenza. The available evidence in favour of Pfeiffer's bacillus as a prime factor, while convincing as regards the presence of an organism of this group in a large proportion of the cases, and also of its pathogenic significance, was not sufficient to carry conviction that the bacillus in question is the actual micro-organism concerned primarily in influenza. On the other hand, the evidence with regard to the presence at the onset of influenza of an organism smaller even than Pfeiffer's bacillus, and capable of passing through filters that hold up the latter, though promising, was admittedly incomplete, for our knowledge of these filter-passing micro-organisms is in such an early stage that some investigators have still to be convinced of the very existence of such micro-organisms. At the moment, therefore, the precise nature of the primary infective agent of influenza is uncertain, and consequently no secure basis has been established for achieving the specific diagnosis, prevention, and treatment of this disease on lines comparable to those available and already exploited with greater or less success in the case of pestilences such as plague, cholera, and infections of the enteric group.

In these circumstances a warm welcome is to be extended to the careful and systematic researches of Dr. Martin Kristensen,<sup>2</sup> of the State Serum Institute of Copenhagen, on the group of bacteria of which Pfeiffer's bacillus is the most important and best known representative. This monograph well maintains the high standard we have learnt to expect of work from Professor Madsen's well known institute. It is ably and critically written in the English language, and is subdivided into five sections, of which the first contains an excellent historical review of the literature concerning the characters and classification of Pfeiffer's bacillus, its occurrence and its relation to influenza. The remainder of the work is devoted to the author's own observations. Thus, Section 2 deals with the incidence of Pfeiffer's bacillus, as determined during four successive waves of influenza in Denmark, and also with its distribution in cases of whooping-cough, measles, tuberculosis, meningitis, and in healthy persons. Section 3, the largest and most important contribution, embodies the result of an exhaustive study of the characters of Pfeiffer's bacillus, and prepares the way for Section 4, in which that organism, now thoroughly defined, is contrasted with three other hæmoglobinophilic bacteria submitted to examination in the same manner. The important subject of technique and the conclusions reached by the author are contained in the final section, and the monograph ends with a list of references and three plates illustrating special points in the morphology and manner of growth of Pfeiffer's bacillus. That the scope of Dr. Kristensen's researches has been comprehensive will be realized when it is stated that they extended over a period of four years (1918-22); that this elaborate study of Pfeiffer's bacillus is based on the detailed examination of no fewer than 800 individual strains of that micro-organism; and that the investigation of the incidence of Pfeiffer's bacillus in the healthy Danish population alone involved the examination of over 2,000 persons. In the last direction the medical services of the Danish army and navy afforded him special facilities, valuable help which Dr. Kristensen gratefully acknowledges.

<sup>1</sup> BRITISH MEDICAL JOURNAL, AUGUST 19th, 1922, p. 291.

<sup>2</sup> *Investigations into the Occurrence and Classification of the Haemoglobinophilic Bacteria*. By Martin Kristensen, Chief of Department at the State Serum Institute, Copenhagen. Copenhagen: Levin and Munksgaard. 1922. (Sup. roy. 8vo, pp. 272; 3 plates.)

As a result of this extensive survey the differential value of the special morphological and cultural characters at present regarded as diagnostic of Pfeiffer's bacillus is upheld. The lowest amount of haemoglobin required to obtain growth was about the same for all the strains examined, and the dependence of Pfeiffer's bacillus on haemoglobin still persists after prolonged subculture. The hydrogen ion concentration giving optimum growth, the minimum temperature at which growth occurs, and the degree of resistance to desiccation were approximately the same for all the strains examined; so, too, were the inability to ferment glucose and the failure to exert proteolytic action on gelatin or serum. The majority of strains were destroyed by exposure for half an hour to 50° C., though a few resisted a slightly higher temperature. All of the strains were decidedly aerobic. The majority showed the well known symbiotic phenomenon—namely, an increase of growth around colonies of certain other bacteria—a point to which Kristensen devotes considerable attention and which he finds to be on occasion of definite diagnostic value. Serologically the work of previous observers was confirmed; as almost every strain of Pfeiffer's bacillus was found to differ serologically from the rest no progress could be made in defining this organism either with the agglutination and absorption test or with the complement fixation test. The only positive physiological character that was found to offer promise for this purpose was indol production; the majority of strains from cases of influenza gave a good positive result, whereas a considerable proportion of the strains from healthy persons were negative. But as this divergence could not be correlated with any other constant difference, indol production cannot be employed for splitting up the group now included under the name of Pfeiffer's bacillus. It is interesting to observe that Kristensen investigated examples of Pfeiffer's bacillus from cases of meningitis and found that there was no sufficient reason, serological or otherwise, for regarding these cerebro-spinal strains as different from ordinary examples of the Pfeiffer micro-organism recovered from mucous membranes.

Three organisms of the haemoglobinophilic group were differentiated by Kristensen from Pfeiffer's bacillus for reasons which may briefly be specified. In addition to its failure to grow on ordinary agar, or on agar enriched with ascites fluid, an important negative character of Pfeiffer's bacillus is its failure to haemolyse blood. This negative property, which is remarkably constant, at once distinguishes the true Pfeiffer bacillus from a definitely haemolytic organism closely resembling it in other respects, and occurring in a proportion of normal throats, but not in influenza. It is important to note that Bordet's whooping-cough bacillus, of which 75 strains were studied culturally by Kristensen, was found to be distinguished from Pfeiffer's bacillus not only by the well known circumstance that it grows on ascites agar, but also by the very significant fact that so far as Kristensen's somewhat limited serological studies of this whooping-cough organism went, all the strains of it examined were found to conform to a single serological type. A third representative of the Pfeiffer group present in blenorrhoea of the prepuce of dogs was also studied by Kristensen; while indistinguishable from Pfeiffer's bacillus in other respects, it possessed a higher resistance to desiccation, and was further differentiated by the circumstance that colonies of this dog bacillus were found to promote the growth of Pfeiffer's bacillus, a symbiotic property which colonies of the true Pfeiffer organism do not exhibit for strains of their own species.

The observations of Kristensen on the distribution of Pfeiffer's bacillus derive additional weight from the care with which he defined this micro-organism by the studies referred to. In cases of influenza he found the Pfeiffer organism most often in the first couple of days after the onset. In measles the incidence was similar to that found in influenza, while in whooping-cough he actually succeeded in demonstrating Pfeiffer's bacillus more frequently than in influenza. In a group of seven cases of phthisis with no symptoms of influenza he recovered Pfeiffer's bacillus five times, but he

was unable later on to detect it in five specimens of material from phthisical cavities. Among healthy persons Pfeiffer's bacillus was found to have a wide distribution; the incidence, however, was very variable, ranging in different groups from 8 to 100 per cent. He found that the incidence of Pfeiffer's bacillus in the general population of Denmark agreed excellently with that of influenza; as a direct consequence of each of the four epidemics a marked increase was observed in the frequency of the Pfeiffer organism in the population as a whole, followed by a sharp decrease. In military camps and barracks Pfeiffer's bacillus was more in evidence than in the general population. In persons who had recovered from influenza Pfeiffer's bacillus was found a little more commonly than in others, but it also had a wide distribution among the general population. Kristensen found that Pfeiffer's bacillus was present in the mouths of 5 out of 60 normal guinea-pigs that had recently arrived from Germany, but he failed to find it either in mice or in horses.

Kristensen does not regard Pfeiffer's bacillus as the primary infective agent of influenza. In the light of the whole of the available evidence his view of the activities of this micro-organism is as follows:

"Pfeiffer's bacillus is mainly adapted to living in the mucous membranes of the respiratory tract in man. In healthy persons it is able to exist for a time, but only with difficulty. Its ideal conditions for development are in mucous membranes already in a catarrhal state, but the nature of the infection producing the catarrh is a matter of indifference: it may be influenza taken in its widest sense, whooping-cough, measles, or tuberculosis. Its growth is also favoured, but to a less extent, by infections which involve a more limited area of mucous membrane—for example, angina, diphtheria, etc., or even catarrh produced by non-bacterial causes. The reason why Pfeiffer's bacillus occurs most constantly in whooping-cough and measles is on account of the wide distribution and endemic character of these diseases preparing the soil. The conditions are otherwise in such a pronounced epidemic disease as influenza. Consider such an epidemic in its very early stages. It spreads over a population the large majority of whom do not harbour Pfeiffer's bacillus. In the early cases Pfeiffer's bacillus is only exceptionally met with, but in those patients in whom it is present it will multiply rapidly and spread to others, and also to healthy persons who may become infected with influenza as well as with Pfeiffer's bacillus, or with Pfeiffer's bacillus without developing influenza, for under the new conditions the bacillus is likely to acquire an improved capacity of developing in normal persons. . . . In this manner the bacillus gradually spreads until it is present in almost every influenza patient and in a number of healthy individuals as well. Perhaps this microbe eventually acquires so great an increase in its vitality that it thrives not only in healthy persons, but also may be able by itself to produce infections resembling influenza. When the influenza dies out Pfeiffer's bacillus may exist in normal people for some months still, but as it is incapable of living for a prolonged period as a pure saprophyte it will, as before the influenza appeared, gradually be limited to occurring in endemic diseases."

The advantage of this conception is that, as Kristensen claims, it accounts for the whole of the observed facts; in particular it has the merit of explaining why in certain outbreaks of influenza Pfeiffer's bacillus has not been found when searched for by bacteriologists of great experience in the detection of this micro-organism employing technique that is above suspicion, as proved by the excellent growth of Pfeiffer's bacillus when material containing it is available. Should further investigations substantiate this wide view of the pathogenic significance of Pfeiffer's bacillus it may eventually become desirable, as has been suggested, to change its pre-war name of *B. influenzae* to that of *B. catarrhalis*. The observations of Kristensen, however, fully substantiate the frequency of the occurrence of this bacillus in cases of influenza, and demonstrate in a striking manner the close association between epidemics of that disease and the carrier rate of Pfeiffer's bacillus. Accordingly, the prophylactic use of a vaccine of Pfeiffer's bacillus obtains material support from these comprehensive and well planned studies of recent outbreaks of influenza in Denmark.

SATURDAY, JANUARY 20TH, 1923.

### THE INFLUENCE OF PASTEUR ON SURGERY.

IN an article in this column last week we endeavoured to give some general account of Pasteur's work, especially his earlier work with regard to crystallography and fermentation, and only brief reference was made to the manner in which the lessons to be learnt from his discovery of the specificity of micro-organisms, and his repudiation of spontaneous generation, were applied and extended by Lister to the prevention of wound infections. Pasteur had to meet very great opposition from many quarters, for he was proving that opinions held by the highest authorities in science were wrong; incidentally he upset the beliefs of the chief surgeons of the day, whose practical methods were based on tradition, which their clinical observations appeared to confirm. Pasteur's experiments, as all open-minded surgeons had to recognize, disproved ideas regarding fermentation that had been used to explain inflammation in wounds. Although they themselves did not undertake to cultivate the micro-organisms which occurred in infected wounds, they could not remain unconvinced when these micro-organisms were made visible to them under the microscope (the construction of which was just then greatly improved) and when Lister added demonstration to demonstration that if wounds were kept free from infection they healed speedily in a natural manner.

The most sceptical found it no longer possible to deny specificity, and gradually ceased to talk of dirt in terms implying spontaneous generation, or of the change of one species of micro-organism into another. The old constitutional pathology was reduced to a place of secondary importance. As Pasteur pursued his researches he supplied a new interpretation of the proverb that "the better is the enemy of the good." Lister began his improvements in surgery by seeking to prevent infection of wounds from the air, using chemical antiseptics for this purpose. Pasteur furnished his followers with methods by which the cause of the infection of wounds was traced to the patient's skin, the surgeon's hands and his instruments, as sources of more immediate importance, especially after improvements in sanitation had been made. Pasteur invented in the laboratory the methods of sterilizing fluid and solid materials which gradually were introduced into the practice of surgery. Die-hards had to yield to the fact that infection of wounds was preventable, even when the surrounding circumstances were unfavourable. Pasteur often quoted the remark made in 1667 by Robert Boyle, in his *Sceptical Chymist*, that he who could probe to the bottom of the nature of ferments and fermentation would probably be more capable than anyone else of explaining certain morbid phenomena.

The discovery of oxygen and its properties had supplied the basis of the explanations of fermentation current during the first half of last century. Liebig continued to use such vague phrases as that putrefaction was an inherent tendency to decay. Oxygen, he said, caused a change for which he proposed the term "eremacausis," a word recent dictionaries omit, but which he applied to the slow oxidation and combustion that goes on in the decay of organic compounds at ordinary temperatures. Berzelius explained fermentation as a catalytic process, a term not only vague but erroneous, for it meant a change in composition effected in a body by the mere presence of another which does

not itself undergo any change. Pasteur demonstrated that the decomposition was produced by micro-organisms which did undergo changes. In 1852 Billroth, one of the most prominent surgeons of the day, supported the hypothesis that infection of wounds was due to decomposing materials similar to vegetable poisons (belladonna, strychnine, curare) and to snake poisons. The arguments then used turned on simple methods of filtration and distillation involving a number of fallacies, procedures which Pasteur's manipulations and apparatus superseded.

Nothing was more difficult than to counter the tradition which put the constitutional causation of disease in the forefront, and at the same time ignored causation by contagion and infection. The history of the discovery of the cause of scabies may be recalled because the agent is just visible to the naked eye. Aristotle said (*History of Animals*, v, 31): "Of insects that are not carnivorous, but that live on the juices of living flesh, such as lice and fleas and bugs, all without exception generate what are called 'nits,' and these 'nits' generate nothing. When lice are coming there is a kind of small eruption visible, unaccompanied by any discharge of purulent matter; and if we prick an animal when in this condition at the spot of the eruption the lice jump out." Avenzoar described the little lice, or acari, which creep under the skin of the hands, legs, and feet, causing pustules full of fluid. The insect was drawn repeatedly and with increasing accuracy, and Galès in 1812 was given a prize for observing, through a watch-glass covering the acarus, the actual penetration of the cuticle. Unfortunately some drew cheesemites, or the *Acarus farinae*, and caused confusion. In spite of the numerous observations which had been made, Hebra in 1842, when describing his experience concerning 2,177 cases of scabies out of a total of 2,723 in his skin department, said that there was a special itch dyscrasia which resulted in the spontaneous generation of the insect in the lymphatics; two years later, however, he had reconsidered the facts and accepted the acarus as the cause of scabies.

The size of the anthrax bacillus facilitated its demonstration, for it was readily made visible under the microscope. The disease had long been known to be both contagious and inoculable, and that not only in cattle. Passing by earlier references, it may be noted that Saporita (1624) said that there was a form of carbuncle which frequently attacked butchers and their families, owing to contagion from the skins and offal of diseased sheep. Larrey noted its occurrence in a butcher's family at Paris, and among soldiers at Toulon who had been stung by flies. He was well aware that butchers, tanners, and cooks were more frequently attacked, yet he shut his eyes to the evidence of inoculation and assumed the cause to be foul air, change of weather and season, and the predisposition of the individual, both in men and animals. In 1838 Delafond saw little rods in the splenic blood, and this was again noted by Pollender in 1849 and confirmed by Davaine. Delafond carried out a number of inoculations on animals. Yet it was not until 1860 that Davaine, after reading Pasteur's paper on butyric acid fermentation, in which it was proved that organisms caused the fermentation, began to connect the rods with the cause of anthrax and to resume experiments on the subject. These in turn attracted the notice of Dr. William Budd of Bristol, who, at the meeting of the British Medical Association in London in 1862, described for the first time the occurrence of malignant pustule in England.

Lister, after his appointment in 1860 to be Professor of Surgery in the University of Glasgow and surgeon to the Infirmary, began to teach that the primary cause of suppuration in wounds was the decomposition brought

about in them in some way by the air, in contradistinction to the theories which referred to changes in the blood. The risk of infection through the air at first formed the basis of the practice of subcutaneous surgery. A crucial instance was the difference between a crush of the thorax causing fracture of ribs, pneumothorax, and surgical emphysema, and a penetrating wound of the chest. Following upon that a parallel may be drawn between the researches of Pasteur and the institution by Lister of his antiseptic system. Many surgeons of the first rank, however, continued to express satisfaction with what they called "cleanliness." Those who recall the controversy recognize that Lister directed the surgeon's primary attention to the methodical prevention of infection. At one of his demonstrations to the British Medical Association he said: "In order, gentlemen, that you may get satisfactory results with this sort of treatment, you must be able to see with your mental eye the septic ferments as distinctly as we see flies or other insects with the corporeal eye. If you can really see them in this distinct way with your intellectual eye, you can be properly on your guard against them; if you do not so see them you will be constantly liable to relax in your precautions."

Lister learned from Pasteur's experiments that putrefaction and fermentation were set up by minute living organisms, and that the idea that the cause lay with the oxygen or some gaseous constituent in the atmosphere was erroneous. Without neglecting precautions coming under the head of cleanliness, Lister directed his attention to the exclusion or destruction of living particles floating in the air. From that he developed his antiseptic system—the application of solutions of carbolic acid to the wound, the carbolized dressing for covering the wound, the steeping of the silk or catgut ligatures, the covering of the instruments in carbolic acid solutions, and the spray to protect from the surrounding air during the operation. Now Pasteur's researches least supported Lister as regards the spray and the application of carbolic acid to previously uninfected wounds, and as a matter of history these were the first parts of the system to fall into disuse.

Pasteur originated the researches which led up to the recognition of streptococci and staphylococci as the chief infective agents of wounds. He intervened first in the discussion as to the cause of the fatal kinds of puerperal fever, such as are now recognized to be set up by haemolytic streptococci. Semmelweis had made a statement of a limited character, that the infection was due to a miasma given off by lying-in women and their infants, particularly after death. It was "infant miasma" infecting the slight wound of his finger whilst operating on a newborn infant which started the deterioration of his health. There had been repeated discussions, in Paris especially, on the so-called epidemics in maternity hospitals, and at one of the debates on the subject in 1878 Pasteur interrupted the speaker, saying, "None of the things that had been enumerated caused the epidemics, but it was the nursing and medical staff who carried the microbe from an infected to a healthy woman." This was indeed a provocative statement, to which the speaker retorted that he feared the microbe would never be found. Pasteur thereupon drew on the blackboard the chain-like organism, saying, "There, that is what it is like." When visiting by invitation a lying-in hospital he declared that all the soiled linen should be put through a sterilizing apparatus. He pricked the finger of a woman suffering from puerperal fever and demonstrated the chain-like organism in the blood. A worker in Pasteur's laboratory suffered from boils; Pasteur isolated from the furuncle the

microbe by growing it in sterilized broth, and confirmed the observation in two other cases. He was present when Lannelongue, at the Trousseau Hospital, was operating on a little girl suffering from acute osteomyelitis. He took some of the pus and isolated the same organism as in the cases of furuncle. "It may," said Pasteur, "be affirmed at first sight that osteomyelitis is the furuncle of bone." Early in 1881 Ogston described in the *BRITISH MEDICAL JOURNAL* how he had found the staphylococcus in every acute abscess.

Then followed the International Congress in London in the summer of 1881, which marked the general acceptance of the researches of Pasteur, Koch, and others, expressed on behalf of surgeons headed by Lister, Lucas-Championnière, and Volkmann. The cultivation of micro-organisms on solid artificial media, and the demonstration of the organisms rendered visible under the microscope by staining, afforded indisputable evidence; in the surgical discussions on the same occasion the success of Lister's antiseptic methods was amply proved. Modifications subsequently introduced were founded upon the sterilizing methods invented by Pasteur. In 1878 he had recommended the flaming of instruments, the sterilizing by moist heat of tow, wool, and pads (used instead of sponges), of dressings and bandages, and the employment of water sterilized by boiling under pressure at 110° to 120° C. In 1882 Neuber of Kiel, among others, set himself to test the sterility of everything connected with surgical operations. The researches of Schimmelbusch and their practical application were fully demonstrated at the International Medical Congress in Berlin in 1890. The laboratory methods employed by Pasteur had become, and continue, an essential part of surgical apparatus.

On December 27th, 1892, Pasteur had reached his 70th year, and a great ceremony was held at the Sorbonne, when Lister delivered an address in French, which is to be found in full in Sir Rickman Godlee's *Life of Lister*. The account is illustrated by a photograph of the central portion of Rixen's picture representing the scene which followed: "M. Pasteur se lève pour embrasser M. Lister. L'étreinte de ces deux hommes était comme la représentation vivante de la fraternité de la science dans le soulagement de l'humanité."<sup>2</sup>

## WAR INJURIES AND LIFE ASSURANCE.

War casualties—both surgical and medical—have presented many problems to those responsible for the medical side of life assurance. In all such cases the difficulty lies in the attempt to steer an even course between two opposing interests—that of the proposer on the one hand, of the insurance company on the other. In the ultimate issue these interests tend to become identical: the prosperity of a company depends on the wise medical selection of its policy-holders, who, in turn, provided their policies are participating ones, profit by the company's prosperity. But when the medical assessor is confronted with an individual proposer in impaired health, his problem is as indicated—to advise terms of acceptance which, while giving the company reasonable protection, shall be equitable to the proposer. How is he to arrive at his decision? In theory he should have at his command the results of actuarial mortality investigations of groups of people suffering from the impairment in question. For example, to assess a case of "foreign body in the lung," he should have a mortality table showing the experience, in the form of the ratio of "actual" to "expected"

<sup>1</sup> *The Collected Papers of Joseph, Baron Lister* (Oxford: Clarendon Press, 1909), p. 258.

<sup>2</sup> Pasteur rose to embrace Lister. The embrace of these two men was, as it were, a living picture of the brotherhood of science in its effort to relieve humanity.

deaths in successive years, for a group all suffering from this condition and large enough to exclude the influence of accidental factors. In point of fact, for the great majority of impairments, such information is unavailable, and the assessment of the risk becomes almost entirely an empirical process, depending upon the experience and judgement—not infrequently also upon the prejudices—of the individual assessor. It is particularly in the case of war injuries that the data are so scanty: the number of cases of impairment of this type coming for insurance under normal peace conditions has been so small that the actuarial experience relating to them is almost *nil*.

It is not surprising, therefore, that the Assurance Medical Society has devoted considerable attention to the question, and its members have discussed the problems arising from the war on several occasions during the last four years. At a recent meeting papers on this subject by Mr. W. McAdam Eccles and Mr. G. E. Gask gave rise to an interesting discussion. The former, in his paper, "Further experiences of war wounds in general in relation to life assurance," makes an heroic attempt to classify all war injuries, according to their topography and chief features, and to indicate how these should be regarded for life insurance purposes. On the whole, his views appear to have been generally approved by the other members taking part in the discussion, though naturally there was some criticism on points of detail. At first sight, especially to those who have worked on Pensions Boards, some of his recommendations may seem a little unexpected, but the problems are, of course, fundamentally different in the two cases. The Pensions Board is concerned almost entirely with the man's capacity for work; the insurance assessor, on the other hand, has regard only to the "expectation of life." Hence a man who has been blinded by loss of both eyes is assessed for pension at 100 per cent., while, for life assurance purposes, he will be accepted, if well in other respects, with only a small addition to cover the extra risk of death from accident. Similarly with the loss of, or injury to, limbs. Thus, with an arm rendered useless through injury to its main nerves, Mr. Eccles rightly recommends acceptance at ordinary rates, as he does also in the case of loss of the whole of the arm, or of one leg from the knee downwards. For the loss of one leg through the thigh or hip, however, he suggests a load of 3 to 5 years' addition to the age. This is perhaps justified on the score of increased liability to accident, but, with the excellent artificial limbs now widely available, a good case might be made out for the acceptance at ordinary rates of all war cases of loss of one leg, provided that the general condition is good. To our knowledge such cases have been accepted by more than one company, and it is improbable that they will be called upon to repent their boldness. With the loss of both legs the case is perhaps rather different. Here Mr. Eccles advises an addition of from 3 to 10 years, according to the level of amputation. It has been suggested that, in addition to the risk of accident, there is a further danger of impaired health in later years owing to the more or less inactive life imposed by the disablement. In the case of many of the young soldiers who have lost two legs this hardly applies. Their activity is wonderful. Many of them, with two artificial legs, manage to walk quite well without even a stick, and with a barely perceptible limp. Such cases might quite reasonably be considered as ordinary risks, particularly for short-term endowment assurances.

One of the most interesting topics in connexion with war wounds is that of epilepsy arising from head injuries. Dr. Aldren Turner, in the discussion, threw valuable light on this somewhat obscure problem. He pointed out that most of the cases of traumatic epilepsy due to war injuries were of the "generalized" type—a general convulsion with loss of consciousness—as opposed to the

"Jacksonian"; if the latter developed as the result of a definite focal cortical lesion, it was usually amenable to surgical treatment. But traumatic epilepsy was, in any case, a comparatively infrequent sequel of gunshot wound of the head. The Ministry of Pensions records gave its occurrence as about 800 in 18,000 cases—that is, about 4.5 per cent. In most of these it developed within eighteen months of the injury, and in the majority of these there was evidence of some predisposing neuropathic history—personal or familial. Dr. Turner thought that, provided the fits occurred only at long intervals—one or two a year—insurance might be effected with only a small addition; if the fits were frequent—several in a month—the proposal should be rejected or, at least, heavily loaded. The outlook in the Jacksonian cases he regarded as more favourable than in the generalized ones, as, apart from the possibility of surgical cure, they exhibited a greater tendency to spontaneous improvement.

Mr. Gask's paper deals with "War wounds of the chest and their late prognosis in relation to life assurance." Its chief interest lies in the consideration of cases of a missile retained in the lung or mediastinum. If the missile is a smooth one, such as a rifle bullet or shrapnel ball, it is less likely to cause trouble than is a jagged fragment of shell. There have been several cases of haemoptysis due to ulceration from such a fragment five or six years after its entry. Such cases should therefore be taken only with a considerable loading, though it was agreed that there is no reason at all to suppose that the presence of these foreign bodies predisposed to the development of pulmonary tuberculosis. Both papers are of great interest and should be of real value to the medical officers of life insurance companies. We should like to give our hearty support to Mr. Eccles's suggestion that, in dealing with these war casualties, the offices should as far as possible give the benefit of the doubt to men who have been disabled in the service of their country.

## ETIOLOGY OF RICKETS.

ALL who are interested in the problem of the causation of rickets will be grateful to Professor V. Korenchevsky for his report on the etiology and pathology of rickets which has just been issued by the Medical Research Council.<sup>1</sup> It is a careful and reasoned summary of the extensive literature dealing with the causation of rickets, followed by an account of the results of his own researches. Those who have studied the literature on rickets will know that it is very scattered and extremely contradictory. In particular, failure to agree as to which bony changes constitute true rickets has been a frequent source of dispute in experimental work upon animals. Professor Korenchevsky gives references to about 400 investigations, and has analysed the results carefully and critically; in many cases where investigators have arrived at conflicting conclusions he is able to show that the experimental or clinical observations are not necessarily contradictory.

The chief points dealt with in the report are the histological changes in the skeleton in rickets and osteomalacia, calcium metabolism in normal and rachitic subjects and the effect of calcium starvation in producing rickets in animals, and the influence of the antirachitic factor and of light upon the development of rickets in animals and children.

The bony changes produced respectively by rickets and by calcium starvation are considered at length. Professor Korenchevsky has performed numerous experiments to ascertain the effect on rats of calcium

starvation, and the resulting bony changes are illustrated by forty-one figures of histological preparations. His conclusion is that "in some cases it may be possible, by calcium starvation, to produce a disease which clinically, chemically, macroscopically, and even histologically, may simulate rickets."

It is usually believed that calcium starvation causes osteoporosis, and that in rickets there is overgrowth of osteoid tissue. Professor Korenchevsky shows that the development of osteoid tissue depends upon the general rate of growth of the organism, and in particular upon the rate of growth of the bones, and that in a growing child rickets causes development of osteoid tissue, whilst if growth has been arrested rickets causes osteoporosis. These conclusions explain a large number of the discrepant results obtained in experimental work, for typical rickets can be produced only when, on the one hand, the deficiency in the diet is sufficient to interfere with the deposition of lime in the bones, but, on the other hand, is not sufficient to arrest growth. The evidence as to the changes in calcium metabolism in rickets is fully considered, and Schabady's view is accepted. This is that the initial change in rickets is a derangement of calcium metabolism, that there is a latent period in which the calcium metabolism is negative, but in which there are no demonstrable bony changes, and that during the later stages, when the bony changes are most manifest, the calcium metabolism is usually positive. The statement that the latent phase of rickets may arise during the first two months of life is very important, for it indicates that ante-natal factors are of importance in the causation of the disease. It is interesting to note that the normal breast-fed infant utilizes nearly 60 per cent. of the calcium in its food, whilst the rickety child may lose as much as one-third of the amount of calcium present in its body at birth. With regard to the influence of phosphorus metabolism upon rickets, the conclusion of McCollum and his co-workers, that the ratio between the amounts of phosphorus and calcium in the diet is of great importance, is quoted.

The influence of an antirachitic factor, possibly identical with vitamin A, upon the occurrence of rickets has been the subject of acute controversy. Professor Korenchevsky reviews the literature and also describes a series of his own experiments on rats fed on diets deficient in animal fats. He concludes that "the influence of animal fat is due to one or more active principles dissolved therein. The action is threefold: (a) to control nutrition and growth of the tissues (including cartilage and bone); (b) to control calcium metabolism and calcium deposition in the skeleton; (c) to maintain the appetite. These various actions are manifested in different degrees in individual experiments, and the disturbance of ossification is modified accordingly. . . . A deficiency of the antirachitic factor in the diet of the mother results in a marked aggravation of the skeletal disorders of the offspring kept on a diet similarly deficient." Professor Korenchevsky rightly emphasizes the important influence of the rate of growth upon the development of rickets, and holds that this factor helps to explain some of the discordant results obtained by different workers. The fact that ante-natal conditions may lead to the development of rickets introduces an element of complexity into this already complex problem. A worker in hospital he is hardly surprised to learn from a review of the literature that light produced fever and demonstrated the blood. A worker in Pasteur's laboratory the extraordinary factors appear to be every factor has v. Moreover, the

discovery of a new factor, such as the influence of a fat soluble antirachitic substance, often invalidates a large number of previous investigations made to determine the influence of other factors.

Professor Korenchevsky has summarized this large mass of confusing literature very clearly and very impartially, and his own experiments throw considerable light upon various important points. It is of course impossible in such a subject to produce conclusions that will meet with universal acceptance, but everyone will feel grateful to the author for having given an orderly review of a difficult subject.

#### VICTOR HORSLEY MEMORIAL LECTURE.

It will be remembered that a committee was formed in 1920 by the friends and colleagues of Sir Victor Horsley to take steps to commemorate his services to science and the empire by the foundation of a lectureship or scholarship bearing his name. The tragic circumstances of his untimely death while on service with the army in Mesopotamia, on July 16th, 1916, are still fresh in memory. He was a pioneer in the research work connected with the surgery of the brain and nervous system, and brilliantly applied his own observations to the alleviation of conditions due to lesions of the brain and spinal cord, especially those produced by tumours and trauma. He was also one of the earliest to study the relation of the thyroid gland to myxoedema, and his investigations of rabies were of the utmost value as proving the possibility of stamping out the disease in Great Britain. He gave time and energy freely to the British Medical Association, in the last reorganization of which he was a prominent figure. Subscriptions were received by the committee from all over the world, and a sum of over £1,000 was collected. The committee, over which Sir Charles Bellance, K.C.M.G., F.R.C.S., presided, and of which Sir Frederick Mott, M.D., F.R.S., was treasurer, resolved that the sum should be invested in the name of a board of trustees, who should triennially appoint a person to deliver a lecture in London under the title of the Victor Horsley Memorial Lecture. It was also decided that no limitation should be placed on the trustees as to the country or profession from which the lecturer should be appointed, nor as to the subject of the lecture. We are now informed by Mr. Edward Domville, who was one of the secretaries of the committee, that Sir Edward Sharpey Schafer, Professor of Physiology in the University of Edinburgh, has accepted the invitation of the trustees to be the first lecturer, and that the lecture will probably be delivered in the autumn.

#### VIRGINIBUS PUERISQUE.

The Board of Education is issuing at the close of this week the report of the Consultative Committee on Differentiation of the Curriculum for Boys and Girls Respectively in Secondary Schools.<sup>1</sup> The Committee, whose work was suspended during the latter half of the war, was reconstituted by Order in Council in July, 1920. Two questions were then referred to it for inquiry and advice: (1) Whether greater differentiation is desirable in the curriculum for boys and girls respectively in secondary schools. (2) What use can be made in the public system of education of psychological tests of educable capacity? The report now published sets out the results of the Committee's inquiries on the first reference. Among those who gave evidence were medical men and women, psychologists, schoolmasters and schoolmistresses, inspectors and representatives of examining bodies, bankers, business men, and employers. Among the appendices is a memorandum by Dr. J. G. Adams, F.R.S., Vice-Chancellor of the University of Liverpool, a member of the committee, on anatomical and physiological differences between the sexes. He considers that the facts justify the conclusions that "girls in general are not so strong physically as boys; that they are more highly strung and

<sup>1</sup> The Collected Papers of Joseph, Baron Listel Press, 1920, p. 256.

liable to nervous strain, which very possibly is associated with the fact that physiologically they are liable to heavier drains upon the circulating calcium of the blood; and that with their thinner blood, with lowered haemoglobin content, after puberty they are nearer to the threshold of anaemia." The recommendations of the Committee include some looking to further inquiries in several directions. Among these are the relative susceptibility of boys and girls to mental and physical fatigue, and the character of the games and physical exercises most suitable for girls of varying ages. It is further advised that research should be undertaken by psychologists and teachers on groups of boys and girls respectively, drawn from secondary schools of different types, in order to collect data in regard to the intellectual and emotional differences between the sexes in their bearing on education and as to the achievements of groups of boys and girls in the various subjects of the curriculum at successive stages of school life. It is also advised that further consideration should be given to the whole problem of the curriculum and organization of junior schools and departments, more particularly in its bearing on the future education of the pupils, especially in girls' schools. We hope to discuss the general features of the report in an early issue.

#### ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

Among the duties cast upon a medical officer of health by successive orders of the Local Government Board was that of making an annual report to the local authority he served on the sanitary circumstances, administration, etc., of his district; the orders enumerated in some detail the information which the report should contain. It was for many years the custom of the medical officer of the Board at the end of each year to address a communication to medical officers of health drawing their attention to the requirements of the latest order and asking for such additional information as the advances in knowledge of public health might suggest. The Minister of Health has altered this procedure somewhat, and the Sanitary Officers Order, 1922, states that the report must contain such information as may from time to time be required by the Minister. In anticipation of the making of this order officials of the Ministry in 1921 conferred with the Society of Medical Officers of Health as to what information might most usefully be supplied. As a result it was decided that certain information which did not vary much year by year should only be inserted about every five years in what would be called a survey report. An agreement was also reached as to what might appear in an ordinary report. At the end of 1921 the Minister accordingly issued a circular in which he particularized the minimum information he considered desirable. A similar circular, dated January 10th, 1923, has been issued with reference to the reports for 1922. It does not differ very materially from the earlier document. It contains a statement not previously made which will be welcomed by medical officers of health, to the effect that the statistical information rendered by the Registrar-General will be distributed at the end of February or the beginning of March. If this promise is fulfilled a medical officer of health ought to find no difficulty in completing his report by the middle of April, and it is pointed out that the value of a report to all those concerned is greatly reduced if it is not completed shortly after the end of the year to which it relates. For many years it was the practice of the Home Office to ask medical officers of health to complete a table relating to the administration of the Factory and Workshop Act, 1901, in their districts. Although this table has been discontinued, it is still the duty of a medical officer of health under Section 132 of that Act to report specifically in his annual report on the administration of the Factory Acts in workshops and workplaces. The specific information now required in the annual report is included under the headings of: general statistics; number of cases of notifiable diseases occurring during the year; causes of sickness; summary of nursing arrangements, hospitals, and other insti-

tutions available for the district; laboratory work; number and details of sanitary staff; housing; and sanitary administration. Under this last heading the medical officer of health is asked for the first time to state what action has been taken with a view to smoke abatement.

#### ERYTHREDEMA OR THE "PINK DISEASE."

ATTENTION has recently been called by Zahorsky to the "pink disease," in a paper contributed to the *Journal of the American Medical Association* (December 9th, 1922). This condition, to which the names erythredema and acrodynia are also attached, is a rare one occurring in children, and was first described in Australia, where it had been recognized for some time before it was formally brought to the notice of the profession in a paper communicated to the Tenth Australian Medical Congress by Swift. The disease usually commences with an erythematous rash of varying character—measly, scarlatiniform, or resembling erythema multiforme. There are also other well marked features, the child becoming fretful, peevish, and unhappy. After a few days the erythematous rash may fade, but tends to reappear. Evidence of some general disturbance is found in the fever—not always present—nausea and general itching of the skin, which, from the consequences of scratching, may become infected by pus cocci. Perhaps the most characteristic features of the disease are the changes in the hands and feet. The hands especially tend to assume a swollen bluish-red appearance likened to raw beef.

#### LES MALADIES PAR CARENCE.

THE term "maladies par carence" has recently been introduced into French literature to denote the group of diseases which includes those known in England as deficiency diseases. "Carence" is an old-fashioned legal term meaning bankruptcy or deficiency, and is derived from the Latin *carere*, to be without, to be destitute of. Professor G. Mouton and Dr. Weill, who introduced the term to medicine, define it as denoting diseases which are not caused by infection or intoxication nor by actual starvation, but which are due to a lack in the food of some substance or substances, a certain minimal supply of which is essential to animal life or health. They emphasize the point that deficiency may be due not only to the lack of some essential substance, but also to the substance occurring in some physico-chemical condition in which it cannot be assimilated. This is probably true, but the distinction between chemical change and an alteration in physico-chemical condition is extremely difficult to establish when considering the absorption and utilization of food substances, and therefore this point does not seem to be of any great practical importance. The inclusion in a common group of all deficiency diseases is, however, a sound suggestion. The rapid recent advance in the knowledge of vitamins and the dramatic nature of many of the new discoveries have focused attention upon the effects produced by vitamin lack, and there is a danger of the term "deficiency diseases" becoming restricted to diseases due to avitaminosis, whereas it is important to remember that the body requires for purposes of growth and repair a certain minimal supply of a large number of substances, and that deprivation of any of these will produce disease. The most obvious example of essential substances which the body cannot produce for itself are such elements as iodine and iron. Knowledge of the power of the body to synthesize organic compounds it needs is limited; we know, for example, that it cannot synthesize certain amino-acids, such as tryptophane and tyrosine, although these are essential components of every cell, and probably there are many other substances of which this is true. If the body is deprived of any essential compound which it cannot synthesize, disease and even death must result, and therefore the possible number of different deficiency diseases is indefinitely large. The types of disease which the French writers include under the term "maladies par carence" are: (a) diseases such as hunger oedema, due to insufficient fats and proteins; (b) diseases such

as pellagra, due to lack of essential amino-acids; (c) diseases due to lack of essential elements—for instance, the endemic goitre due to deficiency of iodides; (d) diseases, such as beri-beri, due to lack of vitamins. Deficiency diseases are probably almost unknown in animals living in natural surroundings, for the process of natural selection ensures that only those types of animals exist that can obtain a satisfactory supply of all their essential food requirements from easily available sources. Deficiency diseases, therefore, chiefly occur in civilized communities, for civilization is an attempt on the part of man to modify his environment, according to his own ideas, and often in defiance of natural forces. The process of urbanization has gone farther in England than in any other community, and this has brought diseases due to vitamin lack into prominence, for a large urban community lives to a considerable extent on food which has been subjected to special treatment to permit of its being transported and stored, and such treatment usually results in the elimination of the vitamins, for they are easily destroyed. Other highly interesting types of deficiency diseases occur, however. The introduction of maize as a staple article of diet in many different regions of the world has been followed in nearly all these regions by the appearance of pellagra; this is believed to be due to the fact that the proteins of maize are deficient in certain amino-acids essential to human nutrition. The inland regions of the United States have been seriously troubled by the appearance of endemic goitre, due to the complete absence of iodides in the soil of these regions; this is a striking example of the unexpected results that may follow the settlement of mankind in a new region. The experience of the past century certainly suggests that fresh advances in civilization may easily entail new experiments in diet which may bring to light new deficiency diseases. The vitamins have been brought into prominence on account of their ready destructibility; if they were not so easily destroyed we probably should not know that they existed. There are probably large numbers of other equally important substances, traces of which are equally essential to life, of which we know nothing because we have not heretofore been so unfortunate as to eliminate them from our diet.

#### THE MICROSPECTROSCOPE FOR THE DETECTION OF BLOOD.

THE value of the microspectroscope in the medico-legal detection of blood was demonstrated by Professor Harvey Littlejohn at a meeting of the Medico-Legal Society on January 16th. The spectroscope was, he said, first used in testing for blood in a criminal case about sixty years ago; it enabled the absorption bands characteristic of the colouring matter in blood to be recognized. With the microspectroscope it was possible to prove the presence of blood by several tests, each corroborating the others. It was sufficient to take only one strand of the cotton, linen, or other fibre which bore the stain, and place it on a moistened microscope slide, when, with the microspectroscope, the two bands of oxyhaemoglobin—one fairly dark, almost at the red end of the spectrum, and the other less definite, nearer the orange—would be seen. Certain dyes, however, gave practically the same spectrum, and therefore this first result had to be corroborated. If a stain was fairly recent, ammonium sulphide might be used as a reducing agent, whereupon the two bands would disappear and their place be taken by one dark band. Having used the ammonium sulphide, a little caustic soda was added, whereupon the spectrum of haemochromogen—the most characteristic of all blood spectra—was elicited. If the small stain, instead of being on a fabric more or less transparent, was on a dark coat, the portion could be soaked in water, and the little hairs with blood particles clinging to them teased out. Having focused one of those hairs under a high power of the microscope, the spectroscope was brought into use, and the sequence of spectra again demonstrated. When the stain was old the

haemoglobin became transformed into methaemoglobin, which had a characteristic spectrum; but here again—following the use of ammonium sulphide and afterwards of caustic soda—possibly the second, and in any case the third in the series of spectra (that of haemochromogen) was obtained. Even from a single haemochromogen crystal the absorption band could be made out. It was possible to carry the test even farther. Having got the spectrum of haemochromogen, the ammonium sulphide and the caustic soda could be soaked out, and sulphuric acid added, giving another spectrum, and a very important one under certain conditions of blood examination, that of acid haematoporphyrin, consisting of one sharp band in the orange and another farther towards the purple. Then, washing the sulphuric acid away and adding caustic soda again, the spectrum of alkali haematoporphyrin was visible. Thus from one speck of blood it was possible to get four or five consecutive spectra, each of them characteristic. Professor Littlejohn added that certain microspectroscopes now produced were perfect instruments, but costly. With a minimum of adaptation, however, it was possible to use a small hand spectroscope; the object having been focused, the spectroscope was attached, making an arrangement capable, if not of the most delicate tests, at all events of some very useful ones. In a brief discussion following the demonstration, Sir William Willcox spoke of the value of the spectroscopic method as a confirmatory test, and Mr. Webster agreed, but thought the chemical test for haemin crystals, provided it was carried out with strong glacial acetic acid, the most important of all. Professor Littlejohn, however, expressed the opinion that the microspectroscope might well supersede all other tests. He regretted that the textbooks gave so little information about the use of the microspectroscope; the current edition of one well known work on medical jurisprudence did not even mention it, and other books gave no details.

#### DR. WALTER ELLIOT, M.P.

THE official announcement was made on January 15th that the Secretary for Scotland has appointed Captain Walter E. Elliot, M.C., M.P., to be Parliamentary Under Secretary for Health for Scotland, in the place of Mr. James Kidd, resigned. Mr. Kidd was one of the six members of the newly formed Government (including Sir Arthur Griffith-Boscawen, Minister of Health) who were defeated at the last General Election. Dr. Elliot graduated in medicine at the University of Glasgow in 1913, and obtained the degree of D.Sc. last year. He served with distinction throughout the war with the rank of Captain R.A.M.C. (Special Reserve); he was wounded in France and won the Military Cross with bar. He has represented the Lanark Division of Lanarkshire since the General Election of 1918, and during the past four years has done admirable work in the House of Commons, serving on many committees and ably representing the medical point of view. Since 1920 he has acted as private secretary to the Scottish Under Secretary for Health; he has been honorary secretary to the Committee of Medical Members of Parliament, and for some time Parliamentary honorary secretary of the Research Defence Society. In virtue of his new appointment Dr. Elliot becomes Vice-President of the Scottish Board of Health—a position of some immediate difficulty owing to the Board's attitude towards certain professional matters, more especially the salaries of public health posts in Scotland. That he will use his influence in the right direction may be predicted from the manner in which he has already handled medical affairs in Parliament and the readiness with which he has always put his help at the disposal of the British Medical Association.

IN response to the second appeal by the officers of the British Medical Association for funds for the relief of starving Russian doctors and their families £267 9s. 6d. has been received. The first appeal produced a total of £1,605. Further subscriptions of 5s., or multiples of 5s., are urgently needed. They should be sent to the Financial Secretary, 429, Strand, London, W.C.2.

## WAR MEMORIAL

TO

MEMBERS OF THE BRITISH MEDICAL ASSOCIATION WHO GAVE THEIR LIVES IN THE WAR,  
1914-1918.

It has already been announced that the Council of the British Medical Association has decided that the memorial to members who gave their lives in the war of 1914-1918 shall take the form of a Book of Honour to be placed in the library, a memorial tablet in the entrance hall, and a small book for issue to relatives describing the Book of Honour.

Mr. F. G. Hallett, Secretary of the Conjoint Examining Board in England, who prepared the illuminated testimonial presented to Sir Clifford Allbutt at the Annual Meeting last year, has generously undertaken, as a labour of love to the profession, to illuminate the roll and superintend the engrossing of the names. He submitted to a meeting of the special committee appointed to make arrangements for the memorial a sketch of the first page or frontispiece of the roll. This bears a very beautifully illuminated dedication, the phrasing of which is reproduced in the accompanying tablet.

The scheme of the illumination was greatly admired and Mr. Hallett was asked to complete it. He also submitted two specimens of a page of the names engrossed; one of these was unanimously preferred, and Mr. Hallett was asked

to arrange that the engrossment should be proceeded with as soon as the list of names could be completed. A list has been prepared which is believed to be complete, but it is of course very possible that some names may have been omitted. The first instalment is printed below, and it is hoped that members will be good enough to look through the list and notify any additions or corrections that should be made, and, in particular, will verify the correctness of the christian names, as in some instances difficulty has been encountered

in ascertaining them. Corrections or additions should be sent as early as possible to Mr. L. Ferris-Scott, Financial Secretary, British Medical Association, 429, Strand, London, W.C.2.

## New South Wales.

### A PRACTITIONER DE-REGISTERED.

A MEDICAL practitioner who had held the appointments of physician to out-patients at the Royal Alexandra Hospital for Children and physician to the Tuberculosis Dispensary, and who had practised in Sydney as a physician for several years, was recently charged before the Medical Board of New South Wales. The charge was that he had made use of his official positions to induce the parents and guardians of the patients to place them under his care as private patients, on the ground that they were suffering from tuberculosis, and that they required special treatment with tuberculin injections, a course of treatment which, he said, they could not obtain at the public hospital. The case was heard before the Board sitting as an open court in accordance with the terms of the Medical Act. The Crown and the defendant were both represented by counsel, and the hearing lasted nine days. The Board subsequently held meetings *in camera*, and it was announced that the charge was held to have been proved, and the name of the practitioner was erased from the Medical Register. The case created a great amount of public interest as the charge had been made in the first instance in the columns of a weekly newspaper.

### ROYAL PRINCE ALFRED HOSPITAL.

The annual report of this institution shows that the past year has been notable for the large amount of work done; in every respect this exceeded the total amount reported for the previous years. The Parliamentary Public Works Committee has recommended the erection of a new veneer block in the lower part of the hospital grounds, at an estimated cost of £36,000. From the statement of receipts and expenditure it appeared that the deficiency (£4,854) was almost exactly the same as in the preceding year; the Board had been able to keep down the expenditure in all directions except in the wages bill, which had increased. The total receipts from donations, subscriptions, and from the auxiliary amounted to £12,660, as compared with £14,192 in the pre-

ceding year. Patients' contributions, however, had risen by £3,000, and the income received from the Government had increased from £50,920 to £52,200.

Mr. Oakes, the Minister of Health, said that in his opinion the present system of government, management, and control of public hospitals would have to be considerably altered in the future. The Government were doing something to assist this institution to carry its financial burden, but he hoped in the near future to ask Parliament for £500,000 to put the hospitals of the State, including the Royal Prince Alfred, on a better footing.

### PUBLIC HEALTH.

At a meeting of the Health Society, Dr. Harvey Sutton, Chief Medical Officer to the Department of Education, spoke of the lack of interest in the cause of the public health. Great Britain, in spite of the huge war debt, had increased the health vote sixfold, but in Australia practically the same amount was allotted as before the war. To preserve health was far more important than to cure disease, and to do this, education, co-operation, and economy were requisite. Efforts were being made in the public schools to teach children hygiene and physical culture. Dr. Sutton also referred to the fact which had been proved by statistics that 10 per cent. of the children of the State died before they reached the age of 5 years. Some means must be taken to prevent this waste of life. At present Australia was far behind Great Britain so far as health legislation was concerned—"in fact we were among the most backward people of the Empire."

### UNIVERSITY OF SYDNEY MEDICAL SOCIETY.

On October 18th a luncheon was held in the Union Hall, under the auspices of the Medical Society, in honour of the several retiring teachers who had been members of the honorary medical staffs of the Royal Prince Alfred and the Sydney Hospitals. The retiring teachers were Dr. F. Antill Pockley, Dr. G. E. Rennie, Dr. Hamilton Marshall, Dr. F. Hall, and Dr. Maguire. The toast of "Our Guests" was proposed by Dr. B. T. Edye, and Dr. Pockley replied. In the course of his speech he referred to his early days as a

student at Edinburgh, and remarked that he considered that the medical course was then, on account of the shorter period allowed for graduation, more arduous than the course in Sydney to day. Dr. Pockley bade farewell with the remark that he regretted that the Senate should insist upon the enforcement of retirement at the age of sixty. He considered that many a medical man might be of the greatest value as a teacher at this stage of his life.

#### CONTROL OF MATERNITY NURSES.

In the annual report of the Director-General of Public Health for the year ending June 30th last reference is made to the control of private hospitals, and the desirability of providing for the compulsory notification of puerperal fever is urged. It is stated that the average number of mothers dying annually from causes connected with childbirth is high in Australia as compared with other countries, and that in comparison with the other States of the Commonwealth New South Wales held an unfavourable position. This state of affairs is attributed to the fact that in this State there is no control over practitioners of midwifery: that any woman, however ignorant or untrained, may take up the work of a midwife, assume the title of "nurse," and incur no legal penalty. The report further states that in all probability outside the registered private hospitals very few of the maternity nurses practising in the country districts have had sufficient training to do justice to the heavy responsibilities they assume, and that even in the metropolis there are far too many untrained maternity nurses in practice.

#### LUNACY LEGISLATION.

In response to a public demand for some inquiry into the present lunacy laws of New South Wales, and the administration of them, a select committee was appointed by the Legislative Council to make inquiries. The first witness examined was Dr. Eric Sinclair, the Inspector-General of the Insane, who was asked to describe the present method of admitting and discharging patients and the methods of treatment; what defects there might be in the foregoing methods; and what improvements he could suggest in regard to existing conditions and accommodation. Dr. Sinclair stated that the method of admission adopted here was practically that in force in all English speaking countries; reactionary methods had been suggested, but the movement of modern thought had been in the direction of making admission to mental hospitals easier, rather than more difficult, so that the mental institution should be used for curative treatment rather than merely for detention only. In reply to a suggestion that there was in the public mind a suspicion that a person might be detained in a mental hospital as a result of collusion on the part of relations or others, Dr. Sinclair stated that there was no place in the mental hospitals for a person whose mind was not affected, that the relations of a patient could at any time obtain permission for a re-examination, and that the friends of a patient might petition a judge of the supreme court for a re-examination. The committee then adjourned, and it was subsequently stated that the Chief Secretary had decided to convert the present select committee into a Royal Commission. The actual composition of the Commission has not yet been decided upon, but there are to be representatives from both Houses of Parliament on it. The chairman has not yet been appointed.

## Ireland.

#### MEDICAL APPOINTMENTS IN ULSTER.

At a meeting of the Ulster Medical Society on January 4th Dr. John Campbell, M.P., read the report of a committee, appointed by the Society on December 15th, 1922, which had agreed to submit the following resolutions, to be laid before the Ministries of Home Affairs and of Finance of Northern Ireland:

1. That the two medical inspectors under the Ministry of Home Affairs should have salaries of £800 per annum, rising to £1,000.
2. That the Registrar-General should be a member of the medical profession, so that the notification of infectious diseases, the statistics of infantile mortality, the morbidity rates in disease, and the influence of occupation and environment upon the nature and incidence of disease, should receive the attention which only a medical man could properly give.

3. That salaries which were being paid to the medical officers in some of the unions in Northern Ireland were still very low, and the Ministry of Home Affairs should be requested to place the salaries of the medical officers in the various unions throughout Northern Ireland on a more uniform and equitable basis.
4. That the actual work of school inspection should be carried out only by full-time medical officers.

The committee recommended that a permanent Medico-Political Committee should consist of: (1) the Council of the Ulster Medical Society; (2) the Council of the Ulster Branch of the British Medical Association; (3) two members from each local medical committee in the six counties of Northern Ireland; (4) one member from the medical faculty of Queen's University, Belfast; (5) one representative from each Branch of the Irish Medical Association in the six counties.

## India.

#### LEPROSY IN INDIA.

The notable advances in the treatment of leprosy have given a great impulse to the campaign against that disease in India. An amendment to the Lepers Act now empowers the provincial governments compulsorily to segregate pauper lepers within their borders. Segregation, however, is hardly practicable, if it be true that the total leper population of India may be estimated, as the *Pioneer Mail* asserts, at from half a million to a million. A much more conservative estimate, that of the Census of 1911, puts the number of lepers in the Indian Empire at 109,094, but the officers of the Mission to Lepers consider this to be under the real number, which, in their opinion, is at least 150,000. In Madras, Bombay, and Bengal schemes for the provision of leper settlements are being considered by the provincial governments, while the governments of the Punjab and the Central Provinces are taking more definite action. Over 6,000 lepers are in the institutions controlled or aided by the Mission to Lepers, and another 2,000 are helped by the Mission in other ways. In Behar and Orissa, for instance, there are eight leper asylums in which there were, last year, 1,967 resident patients; the asylums are supported partly by the Government, partly by local authorities, and partly by the Mission to Lepers. The number of lepers in institutions is increasing, but this is considered to be due to the fact that lepers are now going to them more willingly for treatment.

#### CHEMICAL EXAMINATIONS IN THE PUNJAB.

Lieut.-Colonel J. A. Black, I.M.S., has written a pamphlet dealing in an interesting way with the work of the chemical examination department in the Punjab.<sup>1</sup> In contrast with Bengal, Bombay, and Burma, where the greater part of the chemical examiners' work is done on behalf of the Customs and Excise Departments, in the Punjab medico-legal investigations have always formed by far the larger proportion. In criminal proceedings the position of the chemical examiner is peculiar, for in the great majority of cases he is unable to attend personally (owing to the great distances), and his written evidence, upon which he cannot be cross-examined by the defence, must be accepted. He is compelled, therefore, to adhere strictly to a categorical statement of the results of his analysis, without expressing any opinion, and, as a result, any conflict of medical evidence is avoided. Lieut.-Colonel Black says that, while the incidence of crime, and particularly of poisoning, is far greater in India than in England, the general belief that poison in the East is a highly subtle art in which secret poisons defying detection are employed is without foundation. The would-be poisoner in India has recourse to the crude drugs obtainable from the bazaars or to the poisons growing at his door, poisons well known and used from time immemorial. Nor is any subtlety shown in the amount of poison administered, the work of the analyst being simplified by the fact that the amount usually given is far in excess of that necessary for the poisoner's purpose. In addition to the medico-legal side of his work, the chemical examiner analyses water and foodstuffs for local authorities and government departments, medicines and drugs for civil surgeons and others, and performs miscellaneous examinations of various kinds. The new Government laboratory at Lahore, where this work is

<sup>1</sup> *The Work of the Chemical Examiner's Department in the Punjab*. By J. A. Black, Lieut.-Colonel I.M.S. Lahore: Civil and Military Gazette Press. 1922.

carried out, was recently built and equipped at a cost of about one and a half lakhs of rupees, and is stated to be one of the finest laboratories in India.

#### EDUCATION FOR MEDICAL WOMEN IN INDIA.

It has been decided to establish separate institutions for the training of women medical practitioners in India, and accordingly it is proposed to rent suitable premises opposite the Gosha Hospital, Madras, for the establishment of a women's medical school in that city. The Government has been asked by the Minister of Education to grant an additional sum of Rs. 58,500 for this purpose. At the same time the Minister made the statement that, in 1920, the total number of qualified women medical practitioners in India was only 135 for a female population of more than 21 millions. It is hoped to have the new school ready for occupation July 1st.

## Correspondence.

#### NEW REGULATIONS FOR THE D.P.H.

SIR,—There are certain considerations arising from the new regulations of the General Medical Council for the D.P.H. which seem hardly to have been thoroughly understood by those who are chiefly affected, and which appear to me to deserve discussion.

The Council's new rules will apply after January 1st, 1924. They require that not less than two years shall elapse after obtaining a registrable qualification before admission to the final examination for a Public Health Diploma. The curriculum for the D.P.H. shall extend over not less than twelve calendar months. Six months' practical training under a medical officer of health is an important feature of the new scheme, and the time cannot be reduced by attendance at lectures or by a resident appointment at a fever hospital, as at present. The instruction is to include maternity and child welfare, venereal disease and tuberculosis, food, meat, and milk inspection, etc., all of them more particularly from the administrative standpoint. The examination will consist of two parts, Part 1 covering bacteriology, parasitology, chemistry, physics, meteorology, and climatology; Part 2 includes hygiene and sanitation, epidemiology and infectious diseases, sanitary laws and vital statistics, and public health administration.

At present a candidate may, if he satisfies the necessary tests, obtain a Diploma in Public Health within nine months of his name appearing on the *Medical Register*. It is proposed by the new regulations that this be no longer possible and that at least two years must elapse between the two events. It is obvious, however, that a candidate must give up his whole time to the new D.P.H. . . . twelve months is the minimum for the actual curriculum it will be by no means the maximum period for this.

It appears to me from reading the new regulations that any medical man who is ever in future to obtain a qualification in public health must obtain it in the period immediately succeeding his qualifying in medicine; in other words, he must make up his mind while still a medical student that he intends to make his career in public health. No longer will the general practitioner be able to work for his D.P.H. while actually engaged in general practice, as is often done nowadays by those within reach of the necessary facilities. What is to be the result? Is the part-time medical officer of health, who does such valuable public work in the small towns and rural districts, to be encouraged to hold his appointment without any special public health qualification? Or is he to be abolished and his duties merged in those of the full-time assistant medical officers of health for the county in which his area is situated?

At the present time there are in Great Britain rather under 1,000 full-time medical officers of health (and assistant medical officers of health), while there are over 1,200 general practitioners who hold part-time appointments as public health officers. Detailed statistics for the whole country are not available at the moment, but the following details for Wales for 1921-22 are interesting upon this point, and show the present tendency:

Of the thirteen county medical officers of health (each of whom possesses the Diploma in Public Health) twelve are also school medical officers. Only one officer gives his whole time solely to the duties of county medical officer of health. The remaining twelve are also full-time officers, but in addition to

school medical work they act in other capacities—for example, as medical officers for maternity and child welfare, for venereal diseases work, or under the Mental Deficiency Act, 1913.

In the county boroughs, municipal boroughs, urban and rural districts, 141 officers (21 of whom devote the whole of their time to the office of medical officer of health, or to that office and other duties of a similar nature) were in office at March 31st, 1922, 120 being also in private practice. Twenty-nine of these officers performed the duties of medical officer of health for more than one sanitary district. Each of three rural districts has two part-time medical officers of health. Thirty-three of these 141 medical officers of health possess a Diploma in Public Health in addition to the other statutory qualifications.

During the year there were two instances in which full-time service was substituted for part-time service.

My suggested remedy is that there should be two distinct grades of special qualifications in public health: one that should be held, as a rule, by the general practitioner who wishes to hold a part-time appointment (on the lines of the present D.P.H. regulations), and another, on a higher standard, which should approximate, not to the 1924 regulations for the D.P.H. of the General Medical Council, but to an even higher standard—similar to that of the B.Sc. in Public Health which is granted by certain universities. At Edinburgh University, merely to take an example, candidates for the degree of B.Sc. in Public Health cannot sit for the second (final) examination sooner than eighteen months after having taken their degree in medicine, nor sooner than six months after having passed the first examination for B.Sc. (public health). The curriculum necessary to take this degree ensures that a candidate must give up practically his whole time during eighteen months to working for the degree of B.Sc. in Public Health. For the present Diploma in Public Health of Edinburgh, on the other hand, the course of study extends over nine months; the curriculum is a comparatively full one, but it is certainly not necessary that a candidate should give up his whole time to the work, and it has frequently been obtained by general practitioners.

From the national point of view it appears to me better by far that the general practitioner should be encouraged to take an extra qualification in such a direction as public health, and hold the part-time post of M.O.H. in suitable localities, than that the public health should become more and more an affair of purely bureaucratic control.—I am, etc.,

Willesden, Jan. 11th.

W. PATERSON, M.B., Ch.B.

#### HOSPITAL POLICY.

SIR,—The question of the payment of the staffs of voluntary hospitals has been under discussion since December, 1920, and the formation of staff funds has been the approved policy of the Association since the Annual Meeting of 1921. It is not unreasonable therefore to suppose that in those areas in which the hospital staffs are really anxious to be paid some steps will have been taken to establish staff funds. At the Annual Meeting of 1922 the following resolution was carried unanimously:

"That when the Report on Hospital Policy comes before the Divisions for further consideration, statistics should be supplied showing the number of hospitals in which a staff fund has been established."

I would appeal to the Divisions and Branches of the Association to withhold their final decision on the question of payment of hospital staffs until they are in possession of this information. With all the available facts before them they will then have to decide whether it is possible or even desirable at the present time for the Association to legislate comprehensively on the subject.

If it is considered necessary to legislate for every kind of hospital patient it is to be hoped that the amendment of Paragraph 32 proposed by the Council (SUPPLEMENT, November 18th, 1922) is not the last word of the Association on the subject; the further amendment proposed by Dr. Rowland Fothergill in his letter published December 30th deserves careful consideration. The proposal to establish "token" payments is open to three serious objections—namely, (1) The average layman cannot understand the peculiar psychology of an "honorary" staff which demands "token" payments. (2) There are many honorary members of hospital staffs who have not the least intention of attempting to establish any such system, be the "hospital policy" what it may. (3) In the event of the State obtaining control of hospitals at some future date "token payments" would be a far worse handicap to the profession in the struggle for adequate remuneration than were the old "club fees" in the Insurance Act fight.

It is conceivable that Paragraph 33 of the existing hospital policy (BRITISH MEDICAL JOURNAL, SUPPLEMENT, October 7th, 1922) really meets all present requirements, and the much amended Paragraph 32 might safely be "scrapped." The Association would then be in possession of a policy capable of expansion in the light of future experience, and having the advantage at the moment of being comprehensible to the average layman and acceptable to the whole profession.—I am, etc.,

Bury St. Edmund's, Jan. 14th.

BERNARD E. A. BATT.

SIR,—For centuries mathematicians carried on an active controversy in the endeavour to solve the problem of squaring the circle; we bid fair to do the same in the attempt to find a formula that will allow hospital staffs to receive payment for their work and retain the title of honorary. In the narrowest meaning of the term it is probably not possible to find a solution, but payment in one form or another, generally under the name of an honorarium, has long been allowed—in many instances it has been an actual legal payment, certainly not intended to be a full discharge of the hospital debt, merely an acknowledgement, and it is generally agreed that, so long as a staff provide gratuitous advice and treatment for any fraction of their patients, so long may they, to use Dr. Hawthorne's words, "retain their honorary status"; so far, the proposal of the Hospitals Committee is a rational, if not a strictly logical, solution. The Committee's distinction between the classes from whose payments contribution to the staff fund is and is not to be asked is definite: on the one hand are those who directly or indirectly make some payment for services received, on the other those who neither directly nor indirectly make any contribution to the hospital's funds.

If we depart from this definition and attempt to separate those who in any way contribute, we can only do so by drawing quite an arbitrary line. Why should those who contribute anything from one shilling to twenty be exempt, but not those who pay a shilling more than the twenty (I am taking twenty as an average sum for maintenance)? and if the latter are to be assessed, is it to be only the amount in excess of that required for maintenance or the whole sum that is to be drawn on for the staff funds?

There is fairly general agreement that a percentage of the funds derived from a contributory scheme should be paid to the staff fund, but these schemes are largely made up of quite small individual payments. What does it matter whether the individual pays directly to the hospital or indirectly through such a scheme?

The multiplication of classes of patients is becoming such that bookkeeping would be practically impossible; the proposal to divide into two classes—those who pay something and those who pay nothing—is so much simpler as well as more logical that I hope the policy of the Committee will be maintained. Opposition to any innovation there must be, but the more logical and definite the proposal the easier it is to defend and to get accepted.—I am, etc.,

Bradford-on-Avon, Jan. 14th.

CHAS. E. S. FLEMING.

SIR,—I welcome the return of Dr. Hawthorne to this controversy, and prefer his resolution to Dr. Fothergill's, though I would accept either. It must now be obvious that the policy of the Council, which grew steadily more unpopular the better it was understood, has not been improved by mere application of a specious title to a fund the amount of which was no more determined before than it is now. An offering that is tainted at the source is not less repugnant because it is also mean. The plain fact is that the conception of an "honorary" staff whose services shall be unpaid only to those from whom it is found impossible to squeeze a penny, and who would levy toll on money contributed for the bare necessities of life, does not attract. In our private practice we do not do these things, and we desire no lower standard of ethics in our hospital work. Since it is inconceivable that proposals which their own promoters are still, after two years, ashamed to present to their own boards will be approved once this fact is realized, and despite repeated challenges it has not been denied, I will now endeavour to meet the objections which have been from time to time raised to that policy I would promote.

There are places, such as Leicester, where well paid workmen exploit the hospital, refuse almoners, and have paid

representatives on the board. Here the staff are entirely justified in assuming that such beneficiaries, even if they do not otherwise come into the "tariff" group, can pay more than about 30s. weekly, and therefore should be assessed in this class under our scheme. The full Leicester policy would, therefore, still survive in such places, and only there. In other towns, for example Bristol, doubts are entertained about the financial position of young consultants on the staff. Here if the "staff fund" under our scheme should prove inadequate, which has not yet been demonstrated, two courses are open—either to increase the staff, so as to allow more leisure to each for private practice, or to straightforwardly approach the board, state the position, and leave it to those whose business it is to control finance to raise the necessary funds. On the other hand, in a very large number of provincial and all cottage hospitals the juniors on the staff, being in general practice, not only require no such additional emolument, but mostly decline absolutely to beg money from the source suggested by the Council. Again there are hospitals largely supported by workmen's contributions. In these it will, I believe, be almost always the case that there is some definite financial arrangement between contributors and the board. Under my scheme such beneficiaries are assessed, and therefore the policy of the Council presents no advantage. As for manipulation of contributions, although approved societies have been paying for hospital in-patients for two years, and although the sum now allotted by them for such purpose amounts to £175,000 annually, no example of such manipulation can be produced by the Council, the solitary alleged instance being clearly one either of neglect at the hospital or of concealment by the patient. Even such occasional accident might be prevented by more care at the hospital, and an agreement with societies. Not only is there no foundation for the contention of the Council, but the Voluntary Hospital Commission has quite recently sent round a circular complaining that hospitals, even now, are neglecting to avail themselves of the fund freely and unconditionally offered by these societies.

I think I have dealt now with all objections, and commend to the earnest attention of all who would preserve our voluntary system and avoid a disastrous conflict with the laity the resolution of Dr. Hawthorne or of Dr. Fothergill, supplemented by my own amendments to Section VI, Paragraph 19, in confidence that these or others similar will be passed by a sufficient majority at the Annual Meeting at Portsmouth, and the unity of our profession be preserved.—I am, etc.,

Chichester, Jan. 13th.

G. C. GARRATT.

#### WOMEN DOCTORS.

SIR,—Such is the headline of a recent review in the JOURNAL, written by you probably with some distaste, in defect of an alternative; for it is not an elegant title. But the vulgar "Lady Doctor" is still worse, even intolerable. Some while ago I read in another journal a proposal that medical women should follow princesses, countesses, abbesses, actresses and conductresses, and call themselves, as with our allies the Italians, doctresses. Why not? Why make a single and inconvenient exception to a general rule? Signora Montessori has the becoming title of "Doctressa." The difficulty does not arise in France and Germany because of the general affix of Madame, or Frau.

The present indifference of title gives rise to confusion as well as to inelegance. A certain committee had gone far towards the election of a young woman—a "Dr. Wilson," let us say—as house-surgeon in a hospital where the resident staff occupied adjoining bedrooms. And often one finds oneself Dear Sirring a feminine correspondent. For women, unlike men, rarely write a Christian name in full—as, for instance, John P. Robinson—but are content with initials. We used to hear, by the way, of Dr. Euphemia Jones and Dr. Vanessa Smith, but this aid has now disappeared. Indeed some Christian names are indeterminate of sex. Perhaps while the doctorate is a new toy our feminine colleagues are not indisposed to a little camouflage, and to masquerade in names as in cigarettes. But as the novelty of "Doctor" wears off will it not be possible to follow the duchesses, and, instead of "Lady Doctor" or its like, to adopt the prettier name of Doctress?—I am, etc.,

January 11th.

GRAMMATISTA.

## TESTICULAR GRAFTS.

SIR,—In the autumn of last year I read that Docteur Voronoff had been refused a hearing at a Parisian Medical Society on the ground (which was false) that he had already communicated the substance of his paper to the lay press. Several weeks later I heard that the Surgical Section of the Royal Society of Medicine had negatived the proposal that Docteur Voronoff should be invited to come over to England and explain his theories and practice. I therefore determined to go to Paris and investigate matters for myself, saying that there must surely be something of unusual value in the work of a man who was thus being held in the background. I thought of Harvey and Lister. So, just before Christmas, I went. I was fortunate, for on the morrow of my arrival Docteur Voronoff operated on a human patient, into whose tunica vaginalis he anchored portions of the testicle of a chimpanzee, and on the following day he was sufficiently at liberty to spend a considerable time in showing me over his laboratory, explaining his experimental work and displaying his results.

To begin with, a word about the man. Sergius Voronoff, like Metchnikoff, is a Parisianized Russian. He is between 40 and 50 years of age, tall, lean, dark, with the gentle manners of his race. His wife, who recently died, was an American lady with a very large fortune. He holds the position of Director of Experimental Surgery at the Collège de France, a high-browed institution whose officials, being pure scientists, are not allowed to practise for profit. It is thus obvious that the main charge levelled against him—namely, that he is a species of charlatan who is out to exploit the dead or dying sexuality of the senile—is as baseless as it is base. His work is not only unremunerative, it is very costly, and the whole cost of this work is defrayed out of his own pocket.

Many years ago Leland put forward the theory that senescence was due to the dwindling activities of the thyroid gland. Experiments performed on animals convinced Voronoff that, although there was some truth in this view, it represented less than the whole truth. He therefore turned his attention to the only other endocrine which was as accessible as the thyroid to experimental research—namely, the male gonad. By a series of experiments on animals he showed that senescence can be delayed and senility rejuvenated by grafting young testicles into old animals. He also showed that a male animal castrated before maturity, which consequently failed to develop the secondary male characteristics, could be made to develop these characteristics by testicular grafting. Moreover, it became evident that such animals rapidly acquired the power of copulation, though not, of course, of reproduction. Into one normal young male goat he grafted an additional testicle, a third, with surprising results. The animal's horns grew to twice the length of the normal; so did its hair, especially its beard. It rapidly gave evidence of being grossly oversexed and became so combative and *méchant* that it had to be killed. The head and skin have been preserved, to convince the incredulous. Having thus satisfied himself by over 150 experiments of the potency of the gonadal hormone in rejuvenating old animals, Voronoff decided to turn his attention to human beings, in order to see whether in them the hormone acted in the same

way as it did in the lower animals. Into this part of the story I do not at present propose to enter. It is a fascinating story which ought to be, indeed must be, and shall be, told by Voronoff himself. There are, however, two points in connection therewith which may suitably be emphasized here. The one is that the only animals possessing a gonad which is up to the mark of being grafted into human beings are the anthropoid. Or is he to be preferably the chimpanzee. Chimpanzees are expensive, full-time assistants, from £100 to £150, and in all, which his area is situated. Voronoff the expense. At the present time there are a number of full-time medical officers (officers of health), while the tions who hold the officers. Def. available for 1921. operated upon by the cost of the human invalid Voronoff. storing the more sexual capacity. of which he points with the greatest sa. an author, prematurely senile, to fashion among certain ignorant people in all of the French as though they see only sexual element in any and every subject. The above has been to do something the and insular attitude, and to bring the really fine work of a wholly dis-

interested scientist who has conscientiously and generously laboured to increase our knowledge in a department of medicine which is of enormous and ever-growing importance. —I am, etc.,

London, W., Jan. 15th.

LEONARD WILLIAMS, M.D.

A review of a monograph by Dr. Voronoff, giving a detailed account of his theories and methods, was published in the BRITISH MEDICAL JOURNAL of October 21st, 1922 (p. 763).

## OPERATIVE TREATMENT OF FRACTURES.

SIR,—While quite appreciating several of Mr. Charles Firth's points in his interesting letter in your issue of January 6th (p. 43), I would like to say that I purposely made very slight reference to *plating*, or to the details of the *plating* procedure. Nor did I discuss the many different views as to the most suitable type of plates and screws. Probably enough has been written already on that subject. Laue's work, of course, still stands—as I think—unchallenged.

I did emphasize, however, the unsuitability of ordinary silver wire for the usual wiring procedures, and recorded in my paper how we had been led to seek for a material which would justify a larger application of the procedure of wiring. This material we found in the brass wire I referred to, and I can only repeat here what I said in my paper—namely, that we have found it reliable, capable of standing any of the ordinary strains, and pliable to work with. We do not find that it is acted on by the tissues to an extent that can matter.

*Per contra*, I think I may doubt the statement of Mr. Firth that the iron wire he suggests is "not acted on by any of the tissues." We have found steel pins much eaten away even in the space of a very few weeks. Iron must surely oxidize in the tissues.

In any case, the matter can be submitted very easily, and very simply, to the test, either of ordinary experience or of experimental investigation. I am quite open to try some of the wire Mr. Firth suggests if he will be good enough to send me some or to indicate where it may be procured. I beg to thank him for his interesting note.—I am, etc.,

Glasgow, Jan. 10th.

ARCHIBALD YOUNG.

## "ANGELS AND MINISTERS."

SIR,—I welcome the companionship of your leader if it be only for some of the way. We shall have a friendly journey up to this statement: "But entry into the House of Commons turns so largely upon the play of party politics, and the changes and chances of political life are so great, that when a Government has to be formed, a medical statesman of the first magnitude may not be at hand. Such a man may be amongst us to-day; yet when he went out of office it might be said with truth: 'Here was a Caesar! when comes such another?'" But unless the cheerful vigour so generously attributed to me can succeed in dissipating such fears and in making it plain that men of the medical profession are not less versatile than men in other professions, we part company at this "conclusion of the whole matter"—namely, at the doubt expressed whether the medical profession would be able to produce a continuity of medical statesmen of the first magnitude. My answer is that it can, otherwise our great profession is unworthy of its high calling and is in a parlous state indeed.

In casting doubts upon this crucial point your leader is leading the members of the Association and the general public to understand that the medical profession is so limited in resource that it cannot produce men capable of administering affairs which, under proper revision, would be essentially within its own province. Such an admission appears to me to be hopeless, derogatory, and entirely untrue, and never before has the intelligence of a responsible body of men been so grievously assaulted.

Why should your leading article fear that men taken from our own profession should fail, and yet give everyone the impression that no such anxiety is felt about the capability of men taken from other professions? Instead of fighting a fallacy this is to foster one that has prevailed too long.

Does your article desire to attribute to Sir Alfred Mond and Sir Arthur Griffith-Boscawen imperial powers of administrative intelligence denied to medical men? The article concludes with a quotation about Caesar; I will conclude with another which may be as apt and gives expression to my point: "Render unto Caesar the things that are Caesar's." —I am, etc.,

London, W., Jan. 15th.

G. LENTHAL CHEATLE.

## VITAMIN CONTENT OF CERTAIN PROPRIETARY PREPARATIONS.

SIR.—The article in your issue of January 6th on the vitamin content of certain proprietary preparations is so apt to produce a misleading impression in the minds of medical men who prescribe virol for their patients that I trust you will allow me space for a brief reply thereto.

The gist of the paper lies in the demonstration that "in none of the cases examined have the manufacturers succeeded in concentrating vitamins on a commercial scale."

As regards virol, nothing of the sort has been attempted and no such claim has ever been made. Vitamins are but one of the factors in diet; the equally important criteria of balance and digestibility have been considered in its composition.

The value of virol in regard to vitamins lies in the fact that it supplies them in a form suitable for infants and invalids, for whom a diet of "milk, butter, green vegetables, and fruit" would hardly be suitable. As regards milk, it will be noted that the addition of the daily adult dose of virol enables the quantity of the milk (where this is the only food) to be diminished by 17 ounces. This is of value in the numerous cases where it is desirable or essential to reduce the bulk of the fluid intake as far as possible, and constitutes a strong argument for its employment under these conditions.

Comparison is also made with cod-liver oil. It has never been contended that virol consists solely of vitamin-containing fat, and it is thought better to supply a smaller but still adequate proportion of vitamin A in a palatable and digestible form; the formula of virol has received clinical endorsement by the fact that it is used in more than 3,000 hospital and infant clinics. From the vitamin A content in the table the cod-liver oil used was presumably the crude oil, which, though doubtless palatable to a rat, would certainly be rejected by many children and invalids. If, however, it be replaced by some of the "refined" or tasteless substitutes, the prescriber is entirely ignorant of the vitamin content thereof. It is common knowledge, for instance, that "cod-liver oil" is often adulterated with cotton-seed oil, which contains no vitamin A whatever. Moreover, many patients are unable to digest cod-liver oil in any form whatever. In virol, on the other hand, the vitamin-containing fat is presented in a palatable and digestible form.

While welcoming the independent confirmation of the presence of vitamins A and B, we are anxious that it should not appear that we have claimed to supply these in a concentrated form. Virol is a food for use in certain conditions where ordinary diet is inapplicable, and is in no sense a drug.—I am, etc.,

London, W., Jan. 8th.

ARTHUR E. CANNEY,  
Managing Director, Virol Limited.

## Obituary.

ELLIS T. DAVIES, M.D., F.R.C.S. EDIN.,  
Liverpool.

We regret to announce the death of Dr. Ellis Thomas Davies, which took place at his residence in Liverpool on January 5th. During the past six years he had been suffering from bronchitis and emphysema, which restricted his medical work to a great extent, although he still saw many of his old patients down to a period shortly before his death. He was born at Caerwys, in Flintshire, in 1856, and after a sound general education became a student at Edinburgh. He graduated M.B., C.M. in 1877, and M.D. in 1884, and in 1894 he became by examination F.R.C.S. Edin., having previously, in 1893, obtained the diplomas of M.R.C.S., L.R.C.P. Settling down into private practice, he devoted special attention to obstetrics and gynaecology, and was attached to the Ladies' Lying-in Charity, the Liverpool Hospital for Women, and to the Samaritan Hospital for Women, where he held the post of honorary surgeon for some years. He was an active member of the North of England Obstetric and Gynaecological Society, and held the post of vice-president. Dr. Davies published many papers in the *Liverpool Medico-Chirurgical Journal* on diseases of women. These were without exception excellent records of a keen clinician and skilful surgeon.

Dr. Davies was for many years an active member of the Executive Committee of the Lancashire and Cheshire Branch of the British Medical Association; he had held the offices of vice-president of the Branch and chairman of the Liverpool

(Northern) Division. As a member of the Medical Institution he rarely missed its meetings and frequently spoke on subjects of gynaecological interest. A fearless critic, Dr. Davies did not hesitate to express his opinion on modern surgical methods, and on the results of the surgical treatment of cancer. He took much interest in the public life of the city and for some years occupied a seat on the board of the West Derby Guardians. In this capacity he brought to bear his vigorous criticism upon the needs of the sick poor. Dr. Davies was a man of vigorous action and earned the esteem of all those with whom he was brought into contact. He was a kind man, and many good actions he performed by stealth; the soul of honour, devoid of intrigue, he endeared himself to his patients and professional brethren, and his death has come as a sore blow to all his friends. When in committee meetings he may have failed to carry conviction, no rancour was left behind. The funeral took place on January 8th, and many personal friends and representatives of the institutions with which he was associated were present to honour his memory. He was unmarried, and leaves behind a brother, Dr. J. Twiston Davies, who is in practice in Wallasey.

Dr. WILLIAM CARMICHAEL STEEN died at Letchworth, Herts, on January 4th, in his 60th year. He was the eldest son of the late Dr. Robert Steen of the Royal Belfast Academical Institution. He graduated M.D. and M.Ch., R.U.I., in 1886, and practised at Orston Ferry, Lincolnshire, and at Belfast. For many years he was laid aside from active work by spinal caries. He bore his long illness with exemplary patience and cheerfulness under such suffering as would have disheartened a less brave man. Among his many occupations must be included the work that he did for the Braille Library for the blind. He not only mastered the difficulties of Braille and transcribed books by this method but was a recognized instructor in the subject. Dr. Steen was a member of the British Medical Association and was keenly interested to the last in the advances of medical science. He married in 1900 Margaret, youngest daughter of the late William Eaden Lilley of Cambridge, who survives him.

Dr. JOHANNES ORTH, Professor of Pathological Anatomy in the University of Berlin, died on January 13th. He was born in 1847, and was assistant first to Rindfleisch in Bonn, and afterwards to Virchow in Berlin. In 1878 he became professor of pathology at Göttingen, and succeeded Virchow at Berlin in 1902. He was a successful teacher, and the author of several textbooks.

## Universities and Colleges.

## UNIVERSITY OF LIVERPOOL.

THE following candidates have been approved at the examination indicated:

D.P.H.—Christine C. Abernethy, Esther Ashworth, A. E. I. Connolly, C. E. Freeman, A. Speight.

## ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY Council Meeting was held on January 11th, when Sir Anthony Bowlby, President, was in the chair.

Diplomas of membership were granted to 3 further candidates recently found qualified. Diplomas in Public Health were granted to 24 candidates. Diplomas in Tropical Medicine were granted to 13 candidates. Diplomas in Psychological Medicine were granted to 13 candidates.

## Lectures.

The lecture arrangements at the College for 1923 are as follows: January 29th, Professor R. L. Knaggs: Osteitis fibrosa. January 31st, Professor E. M. Woodman: Malignant diseases of the upper jaw, with special reference to operative technique. February 2nd, Professor C. A. Joll: The metastatic tumours of bone. February 5th, Professor H. E. Griffiths: The relation of diseases of the gall bladder to the secretory function of the stomach and pancreas. February 7th, Professor Geoffrey Keynes: Chronic mastitis. February 9th, Professor L. B. Rawling: Remote effects of gunshot wounds of the head. February 14th, Sir John Bland-Sutton: The Hunterian Oration. February 21st, Mr. R. L. Braithwaite: The flow of lymph from the ileo-caecal angle and its possible bearing on (1) the formation of gastric and duodenal ulcers, and (2) the cause of other types of indigestion. February 23rd, Mr. E. R. Flint: Abnormalities of the hepatic and cystic arteries and bile ducts. The lectures, which are free without ticket, will be given at 5 p.m., with the exception of the Hunterian Oration, which will be delivered at 4 p.m.

## LONDON HOSPITAL MEDICAL COLLEGE.

LECTURES on "The mathematical basis of physiological problems" will be given at the London Hospital Medical College by Dr. W. A. M. Smart, at 4.30 p.m. on January 25th, February 1st, 8th, 15th, 22nd, and March 1st and 8th. Attendance at this course is recognized in connexion with the B.Sc. (Honours) Degree in Physiology. Admission is free without ticket.

## Medical News.

A CONFERENCE of staffs of voluntary hospitals in London, arranged by the Metropolitan Counties Branch of the British Medical Association, will be held in the Council Room, 429, Strand, on Tuesday, January 30th, at 4 p.m. The business will include discussion of a report on the scheme of the Hospital Saving Association prepared by the Advisory Hospitals Committee; and the reply of the Hospital Saving Association thereon.

WE are informed by the Cremation Society of England (52, New Cavendish Street, W.1) that the total number of cremations in Great Britain during 1922 was 2,009, a net increase of 87 on the figures for the previous year. While in Greater London there was an increase of 123, there were 36 fewer cremations elsewhere, the crematoria at Birmingham and Sheffield alone showing any substantial improvement on the figures for 1921. Compared with the average of the preceding ten years, the figures for 1922 show an increase for Greater London of 36.33 per cent., and for the Provinces an increase of 18 per cent.

SIR ALMROTH WRIGHT, K.B.E., F.R.S., will give the Friday evening discourse before the Royal Institution of Great Britain on January 26th at 9 p.m., his subject being the machinery of antibacterial defence.

A POST-GRADUATE course on crime and punishment has been arranged for medical practitioners by the Faculty of Medicine of the University of Birmingham from May 7th to 19th inclusive. The course will consist of lectures on crime and punishment, mental defect, and insanity, together with demonstrations at the prison, at Barusley Hall Asylum and at other institutions. The fee for the course will be £5 5s. Further particulars appear in our advertisement pages.

THE Royal Microscopical Society has established a section to deal with the practical use of the microscope in connexion with industrial research. The first meeting will be held on Wednesday next at 20, Hanover Square, when Professor Frederic J. Cheshire, director of the optical engineering department, Imperial College, South Kensington, will take the chair at 7 p.m.

AT the annual general meeting of the Association of Economic Biologists, to be held at the Imperial College of Science on January 26th, at 2.30 p.m., Professor R. T. Leiper, M.D., will give an address on the study of helminthology.

LORD TREDEGAR has given a mansion, Cefr Mabry, near St. Mellons, about four miles from Cardiff, to the King Edward VII Welsh National Memorial Association; it is to be converted into a tuberculosis hospital at a cost of £41,000.

THE anniversary meeting of the Royal Anthropological Society will be held at 50, Great Russell Street, W.C.1, on Tuesday, January 23rd, at 8.15 p.m.

THE election to the vacant scholarship of the Grocers' Company for original research in sanitary science will take place in May next. The Company founded three scholarships, each of the value of £300 per annum, with an allowance to meet the cost of apparatus and other expenses; they are tenable for one year, but renewable for a second or third year. Applications must be sent in before April 1st to the Clerk of the Grocers' Company, Grocers' Hall, E.C.2, from whom a form of application and other information can be obtained.

DR. DAWSON TURNER and Mr. D. M. R. Crombie have each been awarded a Makdougall-Brisbane medal by the Royal Scottish Society of Arts for their paper on "An investigation of the ionized atmosphere around flames by means of an electrified pith ball."

A POST-GRADUATE course will be conducted in the ophthalmic clinic of the Hôtel Dieu, Paris, by Professor F. de Lapersonne, assisted by Dr. Terrien, Dr. Hautant, and others, commencing on Thursday, May 3rd, and extending over May and June. A special certificate from the Paris Faculty of Medicine will be given at the end of the course. The fee is 150 francs, and further information may be obtained from the Secretary of the Faculty of Medicine, Paris.

THE British Association for the Advancement of Science will meet this year in Liverpool from September 12th to 19th, under the presidency of Sir Ernest Rutherford. The presidents of the thirteen Sections include Professor G. H. Nuttall, M.D. (Physiology), Professor F. G. Donnan (Chemistry), Mr. P. E. Newberry (Anthropology), and Mr. C. Burt (Psychology).

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Attilough, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Medisecra, Westrand, London; telephone, 2630, Gerrard.
4. MEDICAL SECRETARY of the Irish Office of the British Medical Association, Dublin; telephone, 4757.
5. Rutland Square, Edinburgh; telephone, 4361, Central.

## QUERIES AND ANSWERS.

## INCOME TAX.

"B. H." enquires whether certain items are admissible expenses in respect of a medical superintendent of an infirmary under a board of guardians.

\*. \* Renewal of medical books, £4 8s. 9d.; professional society subscriptions, £7 7s.; medical journals, £2 2s. We regard these payments as incurred in order to maintain the professional competence of the officer, and therefore analogous to the expense of keeping a car or motor-cycle in a satisfactory state of repair; on these grounds we consider, and have always held, that these expenses should be allowed.

Accountant's fee for completing income tax return, £3 3s. The emoluments of an office are assessable under Schedule E, and the rule is that expenses to be allowable should be incurred wholly, exclusively, and necessarily in the performance of the duties of the office; in our opinion a claim for the allowance of this expense would not be well founded.

## LETTERS, NOTES, ETC.

## INTERNAL USE OF LIQUID PARAFFIN.

DR. JOHN P. (Blackpool) writes that for several years he has given up paraffin as a laxative, and that Dr. Dixon's 30th, 1922, p. 1283) are worthy of serious consideration. I have no facts (Dr. Brown continues) to prove that liquid paraffin is a serious factor in the causation of cancer. It is open to question whether it is a safe laxative for regular use in cases of habitual constipation. Personally, I think it is not. We have reliable and safe aperients in the natural aperient waters, which clear the alimentary canal and leave the mucous membrane clean and fit to carry on its many natural functions. Liquid paraffin coats the mucous membrane with a greasy, non-absorbable surface, and I consider this a serious objection to its use. I am opposed (he adds) to use of the very many coal-tar products if natural drugs can be used.

## VACANCIES.

THE Ministry of Labour for Northern Ireland is about to appoint, for the purposes of the Workmen's Compensation Act, 1926, two medical referees for the county and city of Londonderry, one for the county of Tyrone, and one for Belfast and the county of Antrim. Applications should be made to the Secretary of the Ministry, 7, Upper Queen Street, Belfast, not later than January 31st.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 19.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE  
BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	...
Each additional line	...	...	...
Whole single column (three columns to page)	...	...	...
Half single column	...	...	...
Half page	...	...	...
Whole page	...	...	...

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Letters should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, later than the first post on Tuesday morning, and, if not paid for at the time, should be accompanied by a remittance.

NOTE.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

## An Address

ON

## SOME PROBLEMS OF PROSTATECTOMY.

DELIVERED BEFORE THE HARVEIAN SOCIETY,  
NOVEMBER 16TH, 1922,

BY

SIR JOHN THOMSON-WALKER, M.B., F.R.C.S.,

SENIOR UROLOGIST AND LECTURER ON UROLOGY, KING'S COLLEGE  
HOSPITAL; SURGEON TO ST. PETER'S HOSPITAL.

MANY patients are strangely unwilling to undergo any treatment as a preliminary to operation, partly owing to the desire to get the operation over quickly, and partly to lack of understanding of the gravity of the post-operation complications. The more one sees of prostatic surgery the more one is convinced that many of the complications which follow prostatectomy, some of which may be fatal, are avoidable by treatment before the operation. I will discuss two of these complications.

## 1. BOWEL COMPLICATIONS.

Post-operative distension of the bowel may occur in all degrees of severity, from a slight flatulent distension with difficulty in getting the bowels opened after the operation, to a prolonged distension of the bowel ending fatally from pressure on the diaphragm and interference with the heart's action. It occurs also in all degrees of acuteness or chronicity.

The most striking example of an acute case that I have seen was a man of 60 with a full abdomen and flabby muscles, from whom I removed an enlarged prostate and a bladder growth. The operation was simple, and there was little bleeding. Progress was normal until the fourth day, when there was a sudden pain in the epigastrium in the early morning. This disappeared, but reappeared later, and the abdomen commenced to swell up. The distension became so acute that the skin was tense and glazed. After two hours' acute distension the heart became embarrassed and the patient died. A doctor related a case to me of a woman, aged 50, who suffered from distension of the abdomen uncontrolled by treatment for seventeen years, with about six periods, lasting two or three days, of intermission, during which the abdomen became flaccid. The urine contained pus and blood. *Post mortem* both kidneys were septic and contained stones. This is an example of the condition in its most chronic state. Between these two extremes are the common types, lasting for a few days to ten days. The post-operative cases are usually controlled by treatment, but may cause much anxiety and are occasionally fatal. This post-operative distension in urinary surgery is not confined to prostatic and bladder cases, for it is not uncommon during the first few days after kidney operations, and may occur in septic kidney conditions without operation.

In looking for a cause for the condition we must remember that in kidney operations the colon is stripped from its attachment to the kidney and below this, and there is sometimes a good deal of trouble in separating adhesions at the extraperitoneal aspect of the colon. When we remember also that in septic kidney conditions perinephritis is constantly present, and that this must involve the contiguous wall of the colon, there is no difficulty in recognizing that a local paralysis of the colon is likely to occur leading to distension with flatus, which spreads to other parts of the colon.

In prostatic cases so simple an explanation is not possible. In most of those I have seen the colon was distended, and constipation and hiccups were frequent, but in some cases the stomach was the organ affected, and the distension affected the upper part of the abdomen; in these vomiting of coffee-ground material is usually a symptom. Most of these are cases of enlarged prostate with back pressure on the kidneys, and in some of them, such as that which I have described, uraemic symptoms actually appear. It is likely, therefore, that uraemia may have something to do with causing the condition. But there are cases that occur in younger men without sepsis or uraemia.

Two elements, I believe, enter into the causation: one is flatulent distension of the bowel from intestinal fermentation, and the other is exhaustion of the sympathetic nervous system resulting from uraemia, intestinal toxæmia, or shock. Recently it has been suggested that post-operative dilatation of the stomach is due to dragging on the mesentery by the

small intestine dropping into the pelvis after the removal of large pelvic tumours (Borchgrevink).

Having recognized that such a condition may complicate prostatectomy, is it possible to foretell its occurrence and do something to prevent it? It is, I believe, possible to do so.

There are two different types of patient that are liable to this condition—a thin type and a stout type. Imagine a thin man of 60 with a sallow complexion. He complains of prostatic symptoms; the prostate is enlarged, and there is a varying amount of residual urine. Further investigation shows that he suffers from flatulent indigestion after meals, and has to be careful about his diet; his teeth are probably decayed and there is pyorrhoea; the tongue is coated. The abdominal wall is thin, and should lend itself to easy palpation; but the bowel is full of gas, the percussion note tympanitic, and abdominal palpation is difficult. The other type is a stout, flabby man of 50 or 60, often of the Jewish race. He is fond of rich, fatty foods, and is immoderate in his indulgence in them. The abdomen is prominent, rounded, and tense; there is no pyorrhoea nor decayed teeth. When you meet with an enlarged prostate with either of these types you may expect post-operative trouble from the bowel.

How can we prevent this complication and how treat it when it occurs?

In all such patients I recommend a course of four or five weeks' bowel treatment after the teeth have been carefully overhauled. This question of teeth is very important; it affects not only the bowel risks but also the pulmonary risk. Oral sepsis is the cause in some degree, if not wholly, of the flatulent dyspepsia of the first type of case. It may take five or six weeks or even longer for the dentist to treat the oral sepsis, and there may be considerable difficulty in getting the patient to consent to the dental treatment.

All these intestinal-risk patients, however, do not have decayed teeth and pyorrhoea, and the second type very often have good teeth. The bowel itself must therefore be treated.

I do not presume to instruct such an assembly as this in the treatment of flatulent dyspepsia. Let me mention, however, the lines of treatment that have been most successful in the prostatic cases I have seen. They are the restriction of starchy foods and green vegetables in the diet, bowel antiseptic treatment and bowel tonic treatment, and the avoidance of saline purgatives. Abdominal massage and electrical treatment of the bowel are also useful when the bladder is not distended.

Now let us turn to the post-operative treatment. In the average patient the immediate preparation of the bowel for operation consists in giving a dose of castor oil two nights before the operation and washing out the colon on the morning of the operation. It is, I think, not unusual at present to avoid purgatives altogether before a surgical operation, on account of the bowel disturbance that may be caused. While this may occasionally be good policy where only twenty-four hours is given for such preparation, I cannot but feel that a prolonged and careful treatment of the bowel is a much sounder surgical proceeding and should always be aimed at. After the operation the bowel is left quiet for three or four days, and then a dose of castor oil is given. This is done in order to avoid straining after the operation, which sometimes causes bleeding.

If after the operation the patient commences to show distension of the abdomen or vomiting of dark coffee-ground material, a purge (castor oil) must be given at once. In some cases the stomach is distended and there is persistent vomiting. Here the stomach tube should be passed and the stomach washed out. Sometimes large quantities of dark brown fluid are removed, and the washing will have to be repeated.

Borchgrevink, who looks upon dilatation of the stomach after abdominal operations as due to dragging on the mesentery causing obstruction at the duodeno-jejunal junction, recommends the prone position and elevation of the pelvis; and operation has been recommended with the object of raising the intestines from the pelvis and relieving the drag on the mesentery, and also of removing adhesions. I have not met with a case of post-prostatectomy distension where this procedure held out any prospect of success.

The more common cases have distension of the colon and hiccups, but no vomiting. Pituitary gland is a good drug in these cases, and ergot and strychnine may also be given. A high rectal tube should be passed and the colon washed out, and a tube left for several hours at a time in the rectum. When the patient is stout he should be made to lie on his side,

instead of being propped up in a sitting position, as the passage of flatus is facilitated by this position. Various enemata are given—soap and water, ox-gall, turpentine. Care is necessary in giving enemata of turpentine in old feeble patients. In a hospital patient I once saw sloughing of the whole thickness of the rectal wall in a circular cuff following a large turpentine enema.

## 2. KIDNEY COMPLICATIONS.

Of all the risks to which the sufferer from enlargement of the prostate is exposed those connected with the urinary tract are the most common and also the most frequently fatal. These complications are, however, the most amenable to treatment before operation. They are sepsis and renal inefficiency.

I will discuss renal inefficiency. The patient who suffers from an enlarged prostate has reached the time of life when some interstitial change in the kidney is not uncommon, but apart from those changes which result from the effects of obstruction in the renal tissue it is rare to find a case where chronic nephritis causes anxiety in connexion with prostatectomy. Occasionally such a case is met with, and the condition is much less amenable to treatment than that in which there are kidney changes due to back pressure alone.

With the gradual increasing obstruction of an enlarged prostate residual urine accumulates, and the tension within the bladder, ureters, and renal pelvis increases. This produces interstitial nephritis, the extent of which varies with the duration and degree of obstruction. The renal function in such cases is impaired. The patient suffers from a series of symptoms which are characteristic of this type of kidney disease. There is lassitude, headache, thirst, and loss of appetite. The skin is dry, the complexion sallow, and the tongue is dry, red, and glazed. Constipation is a common feature. In more advanced stages there is loss of flesh, buccal dysphagia, occasional vomiting, and the patient is drowsy during the day and restless at night. The most advanced stage is complete anorexia, and there is frequent vomiting, constant drowsiness with restless delirium at night, and finally coma and death. Twitching of the muscles in a slight degree may be present, but is not a marked feature, and convulsions are absent.

Clinical symptoms are invaluable in the diagnosis of renal inefficiency, but there are cases where they are deceptive, and for over twenty years urinary surgeons have endeavoured to measure the renal function accurately by means of various tests. These have been very fully discussed of late, and I need not discuss them in detail.

The tests that I use at present in prostatic cases are the forced urea elimination test and the estimation of the blood urea. I have abandoned the colour tests in prostatic work, although I not infrequently use indigo carmine in kidney cases. The forced urea elimination is a valuable test of the renal function in these surgical cases, and comes nearer to demonstrating the full functional power of the kidneys than any other that we possess. The significance of the figures produced by this test is variously interpreted. The high figures require no discussion. A kidney which secretes 2 per cent. of urea and over is sound enough for any surgical procedure. It is the low figure that is of importance. What is the reduced urea concentration figure that becomes dangerous?

For some time I found in one of my hospitals that an able house-surgeon, keeping himself abreast of current opinion, was sending up a series of cases for bladder drainage by cystotomy as a preliminary to prostatectomy. These patients were then kept waiting for some weeks or months before the prostate was removed. This was on account of impaired renal function, the urea concentration being 1.4 to 1.6 per cent. Thus a very simple rule of thumb was developing—namely, urea below 2 per cent., drain the bladder and wait; above 2 per cent., single-stage prostatectomy. This arbitrary rule did not appear to me to be justified, and I decided that unless some other factor contraindicating operation was present I would operate in all cases when the urea concentration figure was above 1 per cent. The results have justified this procedure. This does not, of course, mean that all cases with a urea concentration above 1 per cent. are suitable cases for prostatectomy; there are many other factors besides this urea concentration figure to be considered.

In cases where the renal function is severely impaired the blood urea becomes an important indication of the renal function. As Maclean points out, the figures given as normal for the blood urea—namely, 20 to 25 per cent.—are too low in dealing with old men, and a blood urea of 40 to 50 per

cent. may be present without indicating serious impairment of the renal function. I recently operated on a patient whose blood urea was 58 per cent., and who had been refused a single-stage prostatectomy on this account. The patient was in other respects a healthy man, and I disregarded the high blood urea. Recovery from the operation was uneventful.

The blood urea is dependent upon other factors than the urea elimination by the kidneys, such as the amount and composition of the food, the condition of the liver, and the circulation. This test should therefore only be used in conjunction with the urea concentration test. If used apart from the latter it is apt to be highly misleading. A high urine urea with a high blood urea means that the kidneys are healthy, but the supply of urea is excessive. A low urine urea with a low blood urea may mean a lowered renal function. A low urine urea with a high blood urea is significant of serious impairment of the renal function.

It is not possible to take these tests at their face value and use them in rule of thumb fashion as indications as to whether prostatectomy should not be performed in a given case, or to base a prognosis upon them. We have to remember that these tests tell us only the reading of the renal function at the time and under the conditions that the test was made. This does not exhaust the possibilities of variation of the renal function.

There are two important factors to be reckoned with in estimating the value of a low renal function reading—namely, temporary depression and permanent reduction of the function.

Let us take a man with an enlarged prostate and chronic retention of urine with the bladder distended to the umbilicus. The various tests show that the renal function is very inefficiently performed. Now if the decision in regard to operation and the prognosis are based upon the figures shown by these tests, a totally erroneous view of the case may be obtained. A large part of the depression of the renal function may be temporary and due to causes that can with surgical judgement and care be eliminated. What proportion of the reduction of the renal efficiency is due to the existing obstruction and back pressure on the kidney and what to permanent reduction due to chronic interstitial nephritis the tests do not show us, and until this has been ascertained no true clinical picture of the case can be formed.

Another fallacy that has always attended the tests of the renal function is the difficulty in estimating the total functional power of the kidneys. There is a large amount of reserve power in the kidney that is not brought into action under ordinary conditions. In normal kidneys the reserve power amounts to over 50 per cent. of the total renal function. This part of the renal function may be gradually encroached upon by destruction of the renal tissue by disease and the tests of the renal function may show little change. It is this potential renal function that is so important in estimating the risks in a doubtful case.

Many years ago Albarran tried to estimate the reserve renal function by giving diuretics and observing their effect upon the renal function tests then in use. The method was not, however, successful. The forced urea elimination test comes nearer to estimating the reserve function than any other test that we possess.

The decision to operate or to refuse operation in a case of enlarged prostate with impaired renal function rests upon the judgement of the surgeon, and not on the dicta of the laboratory. What the surgeon requires is as accurate an estimate as possible of the renal function at the time of the test. This estimate is most usefully set out in terms of urea elimination and urea retention.

The compilation of formulae is, I think, unnecessary. Maclean uses a urea concentration factor, to obtain which he divides the figure of the urea in milligrams in 100 c.cm. of urine by that in 100 c.cm. of blood. This factor should normally be 60 to 80. When the urea efficiency is somewhat impaired it may be only 30 or 40. If below 20 the condition is generally bad, and if below 10 it is usually severe. I prefer the plain figures of the blood and urine urea with a note as to any likely fallacy that may have affected the individual figures.

When formulae are used various corrections and modifications begin to be added, each with a possible margin of error, until finally we get formulae like those of Koranyi or Ambert, so overburdened by corrections as to have little or no real clinical value.

It is not necessary for a successful prostatectomy that the renal function should be perfect or even approximately perfect. A reduced renal function may be quite adequate for the operation, and the laboratory figures of the renal function tests form only one factor in estimating the prognosis for operation among many, which include the general build and constitution of the patient, the weakness and soundness of other organs, experience of the operator, and, above all, those who will have the immediate care of the patient after the operation and the surroundings in which recovery from the operation will take place.

#### TWO-STAGE OPERATION.

The next question that naturally follows on the estimation of the renal function is whether a one-stage or a two-stage operation should be done.

The advantages claimed for a two-stage operation are: shock reduced; less haemorrhage; sepsis reduced; relief of back pressure; and time allowed for the kidneys to resume their normal function.

The disadvantages of the two-stage operation are: two operations and two anaesthetics; increased time in hospital or home; enucleation of the prostate more difficult owing to rigidity of the abdominal wall; post-operative hernia more frequent.

The two-stage operation has now become very common, and in some parts of America it is the only method practised in all cases.

The disadvantages of the two-stage operation are very obvious and are of such a nature as to appeal to the patient. There must therefore be some very definite advantages in the method before it can be adopted.

In the ordinary straightforward case the two-stage operation is certainly not safer than the one-stage operation. Shock is not a factor in uncomplicated prostatectomy. Rough handling, long exposure of the patient from unmethodical technique, and inadequate anaesthesia may produce it, but these are individual to the surgeon and will as likely attend a two-stage as a one-stage operation.

It is said by some surgeons that they get less haemorrhage in a secondary than in a primary one. Where there is severe cystitis and engorgement of the prostate and prostatic urethra from recent retention of urine this may be so; but in the average case, and in any case where adequate measures for the control of haemorrhage are taken, this is not so and no advantage from the preliminary cystotomy in this respect need be expected. In my own practice I select three very definite types of case for the two-stage operation. These cases form a small minority of the cases of prostatic enlargement, and my routine practice is to perform a one-stage operation.

The cases in which I prefer a two-stage prostatectomy are: (1) chronic urinary retention; (2) sepsis; (3) cases in which catheterization is difficult or impossible and some serious complication, such as bronchitis or pneumonia, is present.

#### 1. Chronic Urinary Retention.

This is recognized as a very dangerous condition. One-stage prostatectomy in these cases is a fatal operation, from suppression of urine due to the sudden fall in urinary pressure. Intermittent catheterization, followed by prostatectomy after some time, is more successful, but it is a dangerous procedure at the best. The danger lies in the introduction of sepsis. With the sudden fall in urinary pressure at the time of catheterization and the rise of pressure during eight or ten hours after the infection very readily ascends to the kidney, causing septic pyelonephritis.

If the bladder is drained it must be slowly emptied and when empty the pressure kept at zero by continuous drainage. This may be carried out by the retained catheter, and if it is possible I prefer it to a preliminary cystotomy, for the intravesical pressure can be let down very gradually, no anaesthetic is necessary, and there is no interference with what will later be the operative area. But the catheter drainage is not always possible. The patient is occasionally intolerant of the catheter, or the urethra may be unsuitable for the retained catheter, or clots or mucus from the bladder may persistently block the catheter. Cystotomy will then be necessary for the drainage of the bladder. This may be carried out under local anaesthesia or under gas and oxygen.

The length of the interval between the preliminary cystotomy and prostatectomy depends on the condition of the kidneys; of this the clinical symptoms and the urea tests

are the guide. The improvement may be rapid, and ten days may suffice for the kidneys to regain an almost normal secretion. On the other hand, weeks or months may elapse before the renal function has so far recovered that the prostatectomy may be safely performed.

#### 2. Sepsis an Indication for a Two-stage Operation.

The combination of sepsis and uraemia from back pressure is known as urinary septicaemia, and there are all degrees of severity of the condition. In some cases of enlarged prostate with urinary infection the bladder is the seat of the infection and the kidneys are very slightly involved. In other cases there is chronic septic pyelonephritis.

In any case cystotomy is the proper method of treatment. Catheter drainage is worthless, for the catheter becomes blocked with mucus and pus, the outlet is not sufficiently free, and the washing cannot be carried out in sufficient volume to be effective. Suprapubic cystotomy is performed and a catheter tied in the urethra. Continuous irrigation is installed and may be carried out for as long as necessary. Continuous irrigation for a week or ten days will clear up the cystitis which is not complicated by some local condition such as stone or diverticulum, or which is not secondary to renal infection. Even when pyelonephritis is present very definite improvement is noted in the renal symptoms when the cystotomy and irrigation are established.

If the renal infection is moderate a stage will be reached when it is safe to perform prostatectomy. But where serious bilateral pyelonephritis is present the preliminary improvement is not maintained, the urine contains a heavy deposit of renal pus, and the symptoms of urinary septicaemia gradually increase and the patient dies.

#### 3. Difficult Catheterization and Serious Complications.

The third indication that I accept for the two stage operation is when there is urgent necessity to relieve the bladder, but there is some complication which makes prostatectomy dangerous. There is no such thing as an urgent prostatectomy. The only urgency in a case of enlarged prostate is to empty the bladder and to provide for drainage. The permanent removal of the obstruction can wait until the patient is in a fit condition for a serious operation.

In most of these cases it is possible to empty the bladder by catheter, and in a case of enlarged prostate I have drained a bladder by retained catheter during the whole course of an attack of lobar pneumonia followed by septic arthritis of the shoulder-joint. But there are cases where it is not easy or possible to do this, either from the difficulty of passing the catheter or of retaining it. In such cases suprapubic cystotomy will overcome the difficulty and place the patient in a position to undergo treatment for the extraordinary complications. Apart from these classes of case I see no necessity to divide the operation of prostatectomy into two stages.

#### EARLY OPERATION.

Fortunately the cases in which a two-stage operation is necessary are becoming fewer than they were some years ago. The two-stage operation is almost always an attempt to repair the mistakes of earlier neglect or unskilful treatment.

In a previous address I ventured to recommend early operation, and was called to task for advocating operation on every old man with a slight increase in the frequency of micturition. This was quite a mistaken view of my meaning. What I suggested then and would like to insist upon now is that every old man with increased frequency of micturition should be carefully examined to see if this frequency is due to changes in the prostate which give rise to obstruction.

Frequent micturition in old men is too often looked upon as the physiological accompaniment of advanced age, and no examination is considered necessary. I believe that this symptom in old men is always the result of a pathological condition, and although the changes in the prostate which produce it do not in the majority of cases progress so as to cause obstruction, still there are a large number of cases where there is advancing obstruction and yet frequent micturition remains the only or the most prominent symptom. In the latter the obstruction may, from the neglect of this symptom, be allowed to advance to a dangerous degree.

#### Wherein lies the Necessity for Early Operation?

We have from time to time reports in the medical press by enthusiastic operators who have successfully operated upon old men of 80 or 90 years, and it is in the experience of all

urinary surgeons that prostatectomy can be successfully done in extreme old age. We know from experience that prosthetic patients who are desperately ill, sometimes apparently moribund, from renal failure due to chronic urinary obstruction or from urinary septicaemia, may with proper strategy in treatment and prostatectomy be restored to health in an almost dramatic manner.

But there is another side to this question. The dangers of prostatectomy in a man over 80 are, other things being equal, undoubtedly much greater than those of an average man of 60. We cannot therefore be indifferent to advancing age as an argument in favour of prostatectomy early rather than late.

Then in regard to the back pressure and the septic cases. The return to health, although dramatic, is at best a comparative one. A careful review of these cases after operation will show that the tale of sepsis does not usually cease with the recovery from the operation. There are still attacks of pyrexia from exacerbation of chronic pyelonephritis, and there may be recurrent attacks of epididymitis, although the continual absorption of toxins kept up by the obstruction has been eliminated by the operation. Even after the removal of the obstruction these patients are never in the condition of health that they would have been had they been able to avoid altogether the period, sometimes extending into years, of urinary sepsis and back pressure. There can, I think, be little doubt that the duration of life in these patients is shortened as a result of the permanent damage done during that time. It is to avoid this period of sepsis and back pressure that I advocate early operation.

It is a common argument that the catheter may first be tried, and then if it fails operation may be performed. Failure here means sepsis of a severe type, often with the inability on the part of the patient or the practitioner to pass the catheter, owing to the increased size of the prostate or the tortuosity of the urethra. When this stage has arrived the damage from sepsis has already been done and is in part, if not wholly, irreparable. Catheter life is commenced with the certainty that in the great majority of cases infection will occur, and the prognosis, immediate and remote, in a patient with enlarged prostate and urinary infection is infinitely worse than that in a patient with enlarged prostate without infection.

A second point in favour of early operation is the "silent" prostate with chronic urinary retention.

Cases are met with where a patient complains of nocturnal incontinence as the only urinary symptom, and on examination the bladder is found distended to the umbilicus. The minor symptoms of uraemia are often present but may have been overlooked. It is not infrequent to find in these cases that the prostate was examined some years previously on account of frequent micturition and was found moderately enlarged, but the symptom subsided and the patient noticed nothing further in regard to the bladder until nocturnal incontinence commenced. These cases are among the most dangerous and difficult to treat in prostatic surgery.

The only way to prevent the development of so grave a complication is to examine all cases of frequent micturition in old men thoroughly, and keep them under observation. If residual urine is found operation should be recommended.

A third reason why operation on an enlarged prostate should not be indefinitely delayed is that malignant changes may take place in a prostate the seat of simple enlargement.

We meet with this change in two forms. In one a large elastic movable prostate shows at one part, on rectal examination, a firm inelastic area on the surface of one lobe, often towards the base. On enucleating the prostate the capsule at this part strips with difficulty, and a layer of leathery capsule is left behind. On microscopic examination this part of the prostate shows malignant changes, while the rest of the enlarged gland shows the usual appearance of cystic adenoma.

The second type of case is where an enlarged prostate shells out satisfactorily and appears to be simple, but the pathologist reports that some part in the interior of the gland shows the histological changes of malignant growth. The number of these cases in the total number of prostatectomies is not great, but it is sufficiently large to make them a factor in advocating early operation. In 100 consecutive cases of prostatectomy for . . . of the prostate the pathologist reported that . . . of malignant change, and 14 were doubtful but were labelled "precancerous." Most of these were prostates of large size. In 11 there was nothing in the clinical examination to raise a suspicion of malignancy. In 4 there

was a small firm area in the region of the seminal vesicle on one side, and in one case the prostate was rather firm in consistence.

Early operation requires definition. I regard all cases of enlarged prostate when the gland is causing sufficient obstruction to produce residual urine of one ounce or more on several examinations as requiring operation. There are some exceptional cases where a large elastic prostate does not produce residual urine. In these cases I also advocate operation. In cases where frequency of micturition is the only symptom, and there is no residual urine and no prominent enlargement of the prostate I do not think operation is necessary.

#### TYPE OF OPERATION.

The operation that Freyer described was a blind operation. The bladder was opened through a small suprapubic incision and the prostate was pushed up by a finger in the rectum while the other hand pushed down the abdominal wall, and the prostate was reached and enucleated with the forefinger. Bleeding was controlled by washing through a catheter with silver nitrate solution. A large tube was placed in the suprapubic wound for four or five days and then removed and the wound allowed to heal.

While recognizing the success and wide application of this operation I have pointed out certain defects to which it is liable. To remedy these defects I have suggested and practise an operation so much modified that I think it may fairly be regarded as a different operation from that practised by Freyer.

The defects to which I have referred are:

1. Certain difficulties in connexion with the abdominal wall.
2. The method of controlling haemorrhage.
3. The frequency and persistence of sepsis.
4. Post-operative obstruction.

Watching Freyer for many years, and practising this operation myself, I have found that in certain cases a considerable amount of force is required to push the abdominal wall downwards towards the pelvis sufficiently far to reach the prostate. This is due either to the thickness of the abdominal wall or to rigidity from spasm of the recti muscles. A hard struggle on the part of the operator and deep anaesthesia are necessary to overcome this difficulty.

The method of controlling haemorrhage in Freyer's operation is primitive and unreliable, and would not be tolerated in any other operation of first importance. Even with every care sepsis was a frequent complication. I shall discuss sepsis later.

In a previous article I described 16 cases of post-operative obstruction following Freyer's operation. Such cases are of sufficiently frequent occurrence to demand some measure of prevention.

#### Open Operation

The operation I perform commences with a suprapubic incision sufficiently long to allow the right hand to pass completely within the muscular abdominal wall and sink into the pelvis. This entirely disposes of the difficulty of approach due to spasm of the recti muscles, and, further, it obviates the necessity for introducing the finger into the rectum, for the enucleating finger now reaches the apex of the prostate without difficulty.

I undercut the skin on either side of the wound for the introduction of supporting mattress sutures at the end of the operation.

The bladder is opened and the prostate enucleated with the gloved forefinger and removed from the bladder. A catgut stitch is placed in each lip of the bladder wound and the patient raised into the Trendelenburg position. The catgut slings are held up and my bladder retractor introduced. This gives a full view of this opening in the bladder base through which the prostate was removed.

All tags, folds of bladder mucous membrane, shreds and semi-detached plaques of capsule, or nodules of prostate and loose strips of urethra are carefully removed. The posterior lip of the opening is examined, and if a definite fold overhangs the prostate cavity a wedge with the base at the edge of the fold and the apex in the middle line is cut out of this.

A haemostatic stitch is introduced on each side of the neck of the cavity with special bladder needles, and a continuous suture of fine catgut is introduced from the right side round the posterior edge and finishing on the left side. This suture includes the mucous membrane of the bladder, the torn edge

of the sphincter vesicae, and the upper torn edge of the remains of the prostatic capsule if, as frequently occurs, this is defined.

Haemorrhage is usually controlled by these sutures. If it still continues, a spouting vessel may be seen deeper in the cavity, and this is clamped and crushed. If, as rarely happens, the bleeding continues, and if there is much venous bleeding from the ascending limb of the prostatic plexus in the anterior wall of the cavity, the catheter is drawn well into the bladder and the prostatic cavity packed carefully round this with iodoform gauze. A tube, rather smaller than the large Freyer tube is placed in the bladder. The retractor blades are changed and used to separate the recti and expose the anterior surface of the bladder. The bladder wound is closed up to the tube with a continuous suture. A small prevescical tube is introduced and the retractor removed. Two catgut mattress sutures are placed through the rectus sheath and recti, and a continuous catgut suture through the cut edge of this sheath.

The objects of this modification of the operation are:

1. To eliminate the difficulty of approach to the prostate.
2. To control bleeding.
3. To reduce sepsis.
4. To prevent post-operative obstruction.

#### SEPSIS.

I have elsewhere<sup>1</sup> discussed haemorrhage and post-operative obstruction, and will here deal more fully with sepsis.

We have long ago left behind the form of sepsis due to staphylococcal infection, where the wound became encrusted with phosphates and healing was delayed and difficult. These infections were undoubtedly due to insufficient preparation of the skin of the patient and of the surgeon's hands, or to instruments. The form of sepsis that occurs during convalescence and after prostatectomy is an infection with *Bacillus coli* or a mixed infection with *Bacillus coli* as the dominant organism.

I. One factor in its production was the rectal finger, combined with the difficulty of approach due to a small abdominal wound. Changing the enucleating hand when one hand has been used to push up the prostate from the rectum must be a dangerous procedure even where washing and a change of gloves has been made. Such a technique would never be tolerated in an intraperitoneal operation, and it ought equally to be abolished in an intravesical operation. Apart from the change of the enucleating hand, the subsequent steps of the operation necessitate the use of both hands, and the danger of infection is equally great at this part of the operation.

In addition to carrying infection there is, I believe, a danger of direct infection through the rectal wall and the wall of the prostatic cavity, due to damage done by forcible manipulation between the rectal and the enucleating finger.

The entire elimination of the rectal finger, and making an abdominal incision sufficiently long to give free access to the prostate so as to permit of gentle enucleation, is, I believe, an important means of prevention of sepsis.

II. A second factor in the causation of sepsis after the operation is the presence of partly detached shreds of mucous membrane and prostatic capsules, prostatic nodules, and strips of urethra. These necrose and form a culture ground for bacteria, and are often discharged some time after the wound has healed as phosphate encrusted masses. In the open operation they are completely removed.

III. There is a tendency for stagnant urine, blood clot, and mucus to collect in the prostatic cavity, and for infection to spread along the column of urine in the tube or alongside the tube from the skin after the operation.

The following measures are used to combat this source of sepsis:

A catheter is tied in the urethra with the eye in the prostatic cavity, and the cavity and bladder are freely irrigated through the catheter daily. Or the urethra and prostatic cavity and bladder are irrigated by Janet's hydrostatic method.

Should there have been sepsis before the operation, or anything to suggest that infection has taken place after the operation, continuous irrigation of the prostatic cavity and

bladder with antiseptic solution is carried out by connecting a reservoir to the catheter and draining the Hamilton Irving box into a pail. The continuous irrigation is continued for several days. As a routine a gauze bag filled with large boric acid crystals is placed in the Hamilton Irving box and renewed twice daily.

With this attention to detail infection has steadily declined in my cases.

IV. Before leaving this subject of sepsis I should like to say a word in regard to the persistence of sepsis which was present before the operation.

There are three important sources of persistent sepsis—namely, pyelitis and pyelonephritis, diverticulum of the bladder, and seminal vesiculitis.

Time does not permit me to deal with these fully, but a short reference may be made to seminal vesiculitis. I believe that in a large proportion of the cases where sepsis persists after prostatectomy this persistence is due to seminal vesiculitis. I have in a number of these prostatic cases removed the seminal vesicles through the floor of the bladder, and will describe the operation fully elsewhere.

It would prolong the prostatectomy too greatly to dissect the seminal vesicles in every septic case at the end of the prostatectomy, but I think the possibility of doing this should be kept in mind.

In two cases of prostatectomy with severe sepsis unaffected by any pre-operation treatment I incised the seminal vesicles through the floor of the bladder by an incision radiating from the centre of the posterior lip of the prostatic opening backwards and outwards to just internal to the ureteric orifice. In these cases I found the vesicles full of pus.

The question should, I think, be raised, in cases of sepsis persisting after operation in spite of energetic treatment, as to whether the vesicles are the source of the infection and if a transvesical operation for their removal should not be done.

#### ANAESTHESIA.

The patients who are submitted to prostatectomy present many difficulties to the anaesthetist, and I will not venture to encroach on his province.

I may, however, make some remarks from the point of view of the surgeon. A considerable proportion of the prostatic cases have a high blood pressure or some degree of myocardial change. Many have emphysema and some have bronchitis.

A pure ether anaesthesia is not suitable for these cases on account of post-operative lung complications. A mixture of chloroform and ether suits them better, but with this also one fears the possibility of post-operative lung troubles.

Gas and oxygen produces a rigid abdominal wall that interferes with the surgical manipulations. This is of less importance in my open operation, where the enucleating hand works inside the muscular abdominal wall and does not require to push it inwards to reach the prostate.

If gas and oxygen is used the patients should have a large dose of morphine, as they suffer greatly from pain on coming round at once at the close of the operation. Where the blood pressure is high, and especially in a case where there is a cerebral haemorrhage, gas and oxygen is an unsuitable anaesthetic owing to the rise of blood pressure it produces.

The anaesthesia which I prefer is spinal anaesthesia with a modified dose of stovaine and just sufficient C.E. to render the patient unconscious. This form of anaesthesia has less severe after-effects than any other, and my colleagues Dr. Hughes and Dr. Shipway have given it for me as a routine method for several years. The most potent objection to this form of anaesthesia is the fall in blood pressure, amounting to 20 to 40 mm. of mercury.

This fall is generally compensated by turning the patient into the Trendelenburg position, but the pressure may again drop at the end of the operation when the horizontal position is resumed. Where the arteries are very rigid and myocardial changes are present this fall in pressure may lead to circulatory failure during the twenty-four or thirty-six hours following the operation, and in such cases I think it is better to avoid spinal anaesthesia.

Local anaesthesia, even when thoroughly carried out, is not a satisfactory method for prostatectomy. The enucleation of the deeper part of the prostate and the tearing of the urethra cannot be carried out painlessly by this method.

<sup>1</sup> British Journal of Surgery, 1923, vol. vii, No. 28, p. 535; BRITISH MEDICAL JOURNAL, August 27th, 1921; Lancet, 1921, i, p. 1603.

## SURGICAL TREATMENT IN CASES OF PULMONARY TUBERCULOSIS.\*

BY

H. MORRISTON DAVIES, M.D., M.Ch., F.R.C.S.,

MEDICAL SUPERINTENDENT, VALE OF CLWYD SANATORIUM; CONSULTING  
SURGEON, UNIVERSITY COLLEGE HOSPITAL, KING EDWARD VII  
WELSH NATIONAL MEMORIAL ASSOCIATION, AND TO THE  
CITY OF LONDON HOSPITAL FOR DISEASES OF  
THE CHEST.

In considering the surgical treatment of pulmonary tuberculosis, the first point that must be discussed is why and when cases of tuberculosis of the lungs should be treated by operative measures. There are three reasons why surgical treatment may succeed in arresting the disease or in prolonging life when other means have failed.

1. If the resistance of the individual patient is such that it failed him only when extremely run down in health, and possibly badly nourished or suffering from great mental strain, the alteration of these conditions by general treatment alone will suffice to make his resistance adequate to deal with the tubercle bacilli, as long as the former bad circumstances do not recur. But if the resistance of the patient is sufficient only so long as the general health and fitness of the individual are really good, then each relapse from good health, every exposure to conditions not eminently suitable, will mean a relapse of the disease in the lungs and a spread of the tuberculous lesion.

It is extremely difficult (if possible) to increase the specific resistance of the patient to tuberculosis; it is a much more feasible proposition to lower the virulence of the tubercle bacilli and in this way *relatively* to increase the patient's resistance. The most efficient means we know of for reducing the virulence of these organisms is by rest—and in the lungs rest is obtained by immobilization by collapse.

2. As soon as the disease has passed beyond the early granulation stage fibrosis sets in and a completely new set of complications arise. The alterations in the bronchial tubes (the secondary bronchiectasis) are the most serious results of the fibrosis, since they in turn are responsible for the retention of secretions and so for the secondary infections. These are the mechanical factors which eventually prove more difficult to treat and a greater menace to life than the organisms which are the original cause of the trouble.

3. The formation of a cavity by the breaking down of a group of neighbouring caseating granulomata, aided probably by the action of organisms other than the tubercle bacilli, leads to a condition which is often disabling because of the retention of secretions, and is dangerous because of the risk of haemorrhage. These mechanical changes can be very little influenced by medical treatment; only the symptoms of the pathological conditions associated with them can be, for the time being, alleviated. By surgical treatment it is possible to collapse the lung, and whenever complete collapse is obtained then not only is that organ put at rest, but the ill effects of the excessive fibrosis are abolished; the shrinkage of this tissue can proceed without involving all the surrounding and adjacent tissues and structures; the dilated bronchial tubes are collapsed and the spaces which retained the secretions are abolished; cavities have their walls approximated and are no longer a source of danger and constant reinfection: they are no longer cesspools for organisms to flourish in and from which to pour out their toxins into the circulation. So far as the collapsed lung is responsible for the symptoms, the cough is abolished and sputum ceases, the fever due to the toxins disappears, and, if haemorrhage has been a symptom, the danger and fear of that too is done away with; this in itself is a great mental relief to some patients.

The general health of the patient can now improve. That, together with the diminution in the virulence of the tubercle bacilli and the relative increase in the resisting powers of the patient, will place him in a most advantageous position for encapsulating the organisms and for making him more secure against a possible renewal of the invasion.

When the collapse is incomplete it may be said that the

advantages obtained are proportional to the degree of collapse. It comes to this, therefore, that once chronic pulmonary tuberculosis has progressed and has caused a degree of fibrosis beyond what can be compensated for by compensatory changes in the remaining healthy lung tissue, the disease may be said to have progressed beyond the early stages, and that from that time onwards, if some permanent improvement is to be looked for, surgical treatment must be considered as an aid to medicinal and to the ordinary sanatorium measures.

Such are the reasons why surgical treatment must be regarded as such an important asset. Now comes the consideration as to when a case is suitable. The chief postulate is that the disease must be unilateral, or that, if there is disease in the opposite side, it is neither extensive nor acutely active; but there are certain exceptions to which I shall refer later. Surgical treatment is indicated—

(1) For the treatment of the primary condition (a) when, although the resistance of the patient is moderate, he must return to work under unfavourable conditions; (b) when the resistance of the patient is insufficient to deal with the tubercle bacilli even under favourable conditions of environment, etc., as is shown either by inability to arrest the activity of the disease or by repeated relapses; (c) when it is imperative to control the risks of infection, as in the case of a mother returning to her home or her children, and in the case of patients (doctors and nurses) whose work brings them into contact with other people who are in indifferent health or in ill ventilated buildings; (d) when it is imperative that the individual should return to work at the earliest moment possible.

(2) When the secondary complications (the mechanical factors) are so advanced that it is impossible to control the symptoms (secondary bronchiectasis and cavity formation).

(3) When it is necessary to control haemorrhage.

(4) When there is tuberculosis of the larynx, which organ is being continuously reinfected from the lung.

(5) When there is pneumonic tuberculosis.

Against these indications for treatment by operation must be placed certain contraindications which are additional to those imposed by the extent of the disease in the lungs. The most important are albumin or sugar in the urine, tuberculosis of the intestinal tract, chronic gastritis, gastroparesis, chronic intestinal stasis of an advanced degree, and (though mentioned last of considerable importance) the temperament of the individual. In an extremely nervous or highly strung person it is probably wiser not to attempt an artificial pneumothorax.

When I was discussing the extent of the disease with which operative treatment could be regarded as practicable under ordinary circumstances, I said there were exceptions. In some cases of fairly extensive bilateral active infection artificial pneumothorax can be attempted.

1. When the disease is very active, with marked secondary change on one side, the prognosis is very grave, because of the hopelessness of producing any lasting improvement in this lung; then, as a desperate remedy, pneumothorax may be attempted, even though there is acute active trouble in the other side, provided that lung has shown any signs of improvement with complete rest in bed, and is not extensively affected by secondary changes.

2. When the collapsed lung has responded to treatment but, later, activity develops, does not subside, or increases in the other lung, artificial pneumothorax may be attempted in this second lung also. In such cases a partial pneumothorax, equivalent to about one-third of each lung, is aimed at. The following is a brief account of a case so treated.

When first seen there was very extensive disease in the right lung, and there was some active trouble in the left also. Collapse of the right lung was undertaken in the first place because of the extreme gravity of the case. At first there was improvement, but this was followed by a serious relapse due to a sudden exacerbation of the disease in the left lung. Last Christmas I despaired of saving her life, but felt there might be a faint hope if a partial pneumothorax could be done on the left side also. I allowed a complete re-expansion of the right lung, and then produced a partial collapse of the left. This bilateral pneumothorax has been maintained ever since. She has since gained 2½ st. in weight, she runs a normal temperature, the last report of her sputum was negative, and she has been able to return home.

My experience is that bilateral partial pneumothorax is a quite justifiable procedure in such cases, as it is also in those in which one lung has been collapsed a year or more and then disease starts or recrudesces in the opposite lung. The lung first treated should be allowed to re-expand to about

\* Being part of a lecture delivered before the University College Hospital Medical Society, October 19th, 1921.  
1. To what extent chronic intestinal stasis and a partial failure of the endocrine glands may be responsible for weakening such resistance, or to what extent the remedying of these pathological states may increase it, I am not able to say, but there must be a great interdependence in the proper functioning of the various organs.  
2. In acute miliary tuberculosis, the fibrosis is insufficient to produce these secondary complications and death results from the acuteness of the tuberculous toxins.

so-thirds its bulk and then a similar degree of collapse of the second lung produced.

Until I began to discuss the very serious type of case for which operative treatment may have to be considered as the last means of saving life I had not particularized as to the method whereby the collapse of the lung should be obtained. For these severe cases I have, however, specifically referred to artificial pneumothorax, as that is the only method of intervention that can be attempted for them. Collapse can be obtained either by intrapleural or by extrapleural separation of the lung from the chest wall, or by letting the chest wall fall in with the lung. Intrapleural collapse of the lung by artificial pneumothorax is the simplest of all these surgical procedures, and is therefore the one which must always be attempted before any other method is considered.

Of the technique, of the difficulties, of the complications, of the variations which are found, making each case almost a law unto itself, I am not going to talk to night, as it is too vast a subject. I do, however, propose to discuss one complication—that is, adhesions—as I have had considerable personal experience in dealing with these, and it is a part of the subject which has been almost entirely neglected in this country except by myself. The type of adhesion under consideration is that which can be seen with the x rays stretching from the lung to the chest wall after partial collapse has been obtained. Such a band, by the pull it exerts on the lung, not only prevents that organ from collapsing to the required extent but tends to keep drawing it out again and to keep open the spaces, encouraging thereby the retention of secretions and the proliferation of the organisms of secondary infection.

These adhesions may be multiple or single, broad or fine. They may consist of fibrous tissue only or have fine blood vessels running along them. The lung at the point of their attachment to it may be drawn out into a cone, thus making the actual band look longer than it really is. The lung at this point may be apparently healthy, it may show tuberculous granulomata, or it may consist of a thin wall cavity. If either of the latter two pathological conditions exists, there is a considerable danger that the lung will rupture if too high a strain is put on it by producing too great a positive pressure in the pleural cavity. None of these details can be known without x rays, and it should be obvious therefore that attempts to collapse a lung without constant radiological control is risking disaster sooner or later. In nearly all the cases sent to me with complications to disentangle and treat, the trouble might never have developed had there been x-ray control.

Adhesions may be found between any part of the lung and the chest wall. By far the commonest position, however, is over the upper lobe, the parietal point of attachment being in the neighbourhood of the first, second, and third ribs. The second commonest site is between the mesial half of the base of the lung and the diaphragm.

Only the finest adhesions can be ruptured. If very fine bands are seen to be interfering with collapse and the lung at the point of their attachment is sound, it is justifiable to attempt breaking them by increasing the intrapleural pressure up to, but not beyond, 40 mm. of mercury. It may not be possible to raise the pressure so high—that depends entirely on the amount of pain and distress produced. One patient will complain of quite acute pain at a pressure equal to 10 mm. of mercury, and another tolerate one equal to 40 mm. of mercury or over, without even discomfort. The rupture will be felt by the patient, who will feel that "something has given way in his chest" and a sudden relief from discomfort or pain, if either were present immediately before. The operator will recognize the rupture by the sudden drop in the pressure and by the increase in the respiratory undulations.

If there is a single adhesion, too stout to rupture, and it can be seen that at its point of attachment to the lung that part of the organ is sound, then, unless rapid and complete collapse is imperative, an attempt can be made to stretch the adhesion by maintaining a steady high pressure in the pleural cavity. An adhesion which is more than about one-eighth of an inch in diameter will not stretch. If the band is too strong or there are more than one, the only treatment is by division. There are three ways of doing this: (1) by tenotomy without other opening through the chest wall than that made by the passage of the tenotome; (2) by the thoracoscope and electric cautery; (3) by thoracotomy and exposure of the adhesion. The first of these is my own method. It cannot be described

as a simple operation, yet in some cases it has proved extremely easy. Everything depends on the position of the adhesion and the possibility of being able to get the adhesion quite tight before attempting to cut it. It is essential for this method that a clear view of the band be obtained with the x rays.

The patient is placed with his back to the x-ray tube. The screen is swung so that it can be turned out of the way or brought in front of the chest and mechanically supported in any position desired. The line of approach to the adhesion is through the intercostal space immediately below the band. The tissues which the tenotome will traverse are anesthetized with 2 per cent. novocain. When this has been done and the cutting edge of the tenotome (which is of a special design) has been passed through the intercostal space into the chest the x rays are turned on and all other lights extinguished. The relationship of the point of the tenotome and of the adhesion can now be made out. The tenotome is pushed towards the adhesion and is moved up and down until it meets the band. The contact of these two can be both seen and felt. The edge of the knife is pressed on to the adhesion, which is then cut through by short sawing movements. If the band has not been made tight by a fairly high intrapleural pressure by an injection of gas a day or two beforehand difficulty will be experienced in cutting through it, as the fibrous tissue is very tough and resisting, and pressure serves only to displace the band downwards and to pull the lung downwards and outwards. The moment the adhesion is cut through the lung will be seen to drop mesially towards the mediastinum.

The opening made by the tenotome is so small that there is rarely more than a little surgical emphysema after the operation. Bleeding from the divided band is only rarely considerable; if it should occur, it will be checked by the increase in the intrapleural pressure. As an illustration that in a simple straightforward case the operation is not a serious one I have had one patient, a woman, who having had her band divided returned home (a distance of twenty-six miles) two hours after, and was at work two days later.

If the adhesion is a tough one some pain will be felt whilst pressure is being applied to it, owing to the pull of the band at its point of attachment to the parietal pleura.

The most likely complications are surgical emphysema and a small pleural effusion or possibly a haemothorax. Of more serious character are those which may result from the lung being injured in the division. This is likely to happen only if a cone of lung has been drawn out by the band and simulates a continuation of the mesial end. If a careful study has not been made beforehand, or if it is impossible to obtain a clear view of the whole length of the adhesion, then it may happen that this portion of lung tissue is cut and a traumatic pneumothorax or a haemopneumothorax or even a pyopneumothorax results. If any of these should happen, the increase in intrapleural pressure will force gas out through the incision in the pleura and produce a considerable increase in the surgical emphysema, whilst the possibility of infection must not be lost sight of.

Jacobaeus advocates the division of adhesions by the electric cautery. This necessitates two openings through the chest wall. Through the one is passed the thoracoscope—on the principle of the cystoscope—by which the adhesion is viewed, through the other the cautery. His results are extremely satisfactory. He is able to divide adhesions which might not be sufficiently visible to attempt by tenotomy, and he can work with a shorter interval of space between the lung and the chest wall. In the division, however, he is greatly hampered by the smoke from the burning of the adhesion, and has frequently to change the air in the pleural cavity so as to be able to see what he is doing. There is also considerable difficulty in retaining the cautery at the correct heat, and to prevent it getting caught by the charring of the tissues. The same complications as those mentioned above may follow on this method of division.

An adhesion which is not accessible for division by tenotomy can be exposed by opening the chest and obtaining direct access to it. This is of course a more serious undertaking, but is quite justifiable when collapse of the lung is essential in the treatment, and is seriously interfered with by a band. It is the method also which may be required when the lung has become torn alongside an adhesion in the case of a spontaneous pneumothorax. The opening cannot close because one side of it is held out by the adhesion and the other pushed away by the pressure in the pleural cavity. The opening even may be valve-like in character, giving rise

to an ingravescent pneumothorax.\* Such an accident may be further complicated by an effusion, at first simple but later infected by tubercle bacilli, by secondary organisms, or by both.

The thorax is opened as near to the adhesion as possible by an incision along an intercostal space, the tissues having been anesthetized by novocain. The ribs on either side are strongly retracted and the adhesion exposed and divided. The wound is then closed, care being taken to secure approximation of the parietal pleura. Should an effusion form after this it is advisable that the patient be placed so that the fluid does not come into contact with the wound. If the fluid is excessive it should be aspirated and replaced by oxygen.

There is one other matter in connexion with adhesions that requires mention. The base of the lung is not infrequently adherent either to the summit of the dome of the diaphragm or to the mesial part of the corresponding half of the muscle. Occasionally it happens that before the intrapleural pressure has been raised sufficiently to collapse the non-adherent part of the lung, the pull on the diaphragm causes distress to the patient, who may suffer from pain and an incessant dry irritating cough; also, if the collapse is on the left side, from vomiting as well. So persistent may these symptoms be, that either the pneumothorax must be abandoned or the diaphragm paralysed by dividing the phrenic nerve in the neck. This will cause complete relief and allow of greater compression of the base of the lung. It must be remembered, however, that the motor fibres to the diaphragm may enter the phrenic nerve through the nerve to the subclavius muscle. In such cases section of the phrenic in the neck is followed by no change in the diaphragm.

Extrapleural collapse of the lung is of value in certain types of cases only. When the disease is localized to one upper lobe and is resistant to treatment, or is advanced and is associated with secondary changes or a cavity, or is causing repeated haemorrhages, then if pneumothorax has been tried and been found to be impossible, local collapse of that lobe can be obtained by displacing the lung, together with the parietal pleura. Such displacement cannot satisfactorily be produced by gas, as there is no sac into which to inject it, and it is too rapidly absorbed by or dispersed through the cellular tissues from which the pleura has been stripped. The displacement has therefore to be maintained by some solid substance, such as paraffin wax or fat.

If the patient has plenty of fat to spare, this is the most satisfactory substance to use, as it is non-irritating and is sufficiently fluid to accommodate itself to the shape of the space into which it is packed.† Failing this, paraffin can be used, but it has the great disadvantage of being in some cases very irritating and of causing an extrapleural serous effusion, which, unless successfully tapped, will distend the wound, discharge through it, and in doing so carry away the paraffin with it. Moreover, when this happens there is the risk that the cavity will become infected.

The whole operation can be done under local and regional anaesthesia or under local anaesthesia with a little chloroform while the upper part of the parietal pleura is being stripped. An incision is made either over the anterior part of the second rib, part of which is removed, or through the anterior part of the second interspace when the ribs are not too closely approximated. The incision is carried down to the parietal pleura, which is carefully stripped away from the overlying tissues up to the apex, and in front and behind, until it is freed over the whole of the upper lobe. When this has been done it will be found that there is a partial collapse of the upper lobe carrying the pleura with it, the collapse increasing during inspiration and decreasing during expiration, whilst a cough will force the lung completely out again. The lung is kept displaced by a copper retractor, and into the space thus formed is put either a mass of fat from the abdomen of the patient or the paraffin. This latter should have a melting point of about 112°F., and be just sufficiently hot to be in a fluid state. It is most important that the patient should not cough from this moment until the wound is firmly closed, as otherwise the paraffin will be forced out and an indifferent collapse obtained. In suturing the wound the closest approximation of the edges must be secured.

Collapse of the lung, together with the chest wall, is a more serious operation and the change obtained is permanent. It is not an operation to advise until all other means have failed, and then only if the conditions and chances are favourable. The class of case for which it is suitable is more limited, and the contraindications are more numerous and more rigid. It is an operation directed to the treatment not so much of the tuberculous lesion as of the secondary complications of that disease. It is of value not for the acute active case but for the patient with long-standing chronic phthisis. Active disease must be, as far as is ascertainable, limited to the one lung, but the presence of a small amount of fibrosis in the other lung is not necessarily a deterrent.

There are two methods by which the lung and chest wall can be collapsed. It can be done either by rib mobilization or by rib resection. Until lately I have been a strong advocate of the former in preference to the latter, as I thought that the resection method was excessively severe. Recent experience has, however, now converted me to this one in preference to rib mobilization. Rib mobilization means two fairly big operations, and the patient is confined to bed usually for a couple of months. Rib resection means one severe operation only and a very much shorter time in bed. The results in both cases are equally good provided collapse of the apex is not essential.

In the operation of rib mobilization collapse is obtained by resecting portions of the posterior ends of the first nine or ten ribs at the first stage, and of the costal cartilages of the fixed ribs together with a wide section of the costal margin at the second stage. The resection of the portions of the first rib is extremely difficult, but unless this is done the result will be disappointing, as the falling down and in of all the other ribs depends very largely on the freedom of the first. As the result of this detachment of the ribs from their posterior and anterior points of fixation and support they drop downwards, they fall inwards, and they tilt downwards and inwards (bucket-handle action). By this change in position they diminish greatly the size of that half of the chest and collapse the lung to about one-third its original size in an adult, and even more so in a child.

The operation of rib resection is done through a single vertical incision extending from the apex of the axilla to beyond the eighth or ninth rib. It is done under a general anaesthetic (chloroform), but immediately before this is started I try to inject each of the first nine intercostal nerves with 5 minims of absolute alcohol close to the angle of the ribs. Even if one does not strike every nerve the shock is considerably diminished and so also is the after-pain.

The ribs having been exposed the periosteum is stripped off each in turn, starting with the fourth or fifth and working first upwards, up to and including the second, and then downwards to the eighth or ninth. The ribs are freed in front as far as the costo-chondral junction and behind to the angle. Each rib as it is freed is divided in the middle, the anterior half is bent forwards and will break off at its junction with the cartilage. The posterior half is then bent back and may snap at the angle. If it will not break as desired, curved bone forceps must be slid down the bone and the rib cut through as far back as possible. It is not feasible to reach the first rib through this incision, but the collapse of the lung and of the chest wall is not, in this operation, dependent on the freeing of it. In most cases sufficient collapse of the upper lobe will be obtained without it, but if it is necessary to get complete collapse of the apex (because, for instance, of a cavity) the first rib must be resected through a separate incision below the clavicle.

The wound is completely closed except for a drainage tube, which is left in for twenty-four hours. It must be remembered that the external surface of the pleura will secrete a serous effusion as well as the inner.

The deformity of the chest is considerable, the whole of the anterior and external aspect, and to a less extent the postero-external aspect, sinking right in. This, however, is not visible when the clothes are on, as these hang from the shoulder, which has been in no way affected.

I have done two cases in the last six weeks and neither of these has had any shock sufficient to give the least anxiety. In the second case, from whom I removed six ribs only, the total amount of bone taken away was almost 3 ft. 6 in. in length when the ribs were placed end to end. Both were up within a fortnight—the second on the tenth day—and the temperature was normal after the third day.

\* The "Spannungs-pneumothorax" of the Germans, in which air enters the pleural cavity from the lung with each inspiration, but cannot escape during expiration.

† On the Continent omentum, lipomata, and fibroids are kept in cold storage, after removal from one patient, in readiness for another.

## DAMAGED LUNGS AND BRONCHIECTASIS.

BY

CLIVE RIVIERE, M.D.LOND., F.R.C.P.,

PHYSICIAN TO CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST  
AND TO EAST LONDON HOSPITAL FOR CHILDREN, SHADWELL.

VERY commonly does it happen that some amount of permanent damage remains as the sequel to an inflammation, of whatever causation, in the pulmonary area; and the more severe and prolonged the attack the greater, as a rule, the disability. Lung tissue, air tubes, and pleura alike may be implicated in different degrees, the end-results showing themselves in fibroid lung, or simple bronchiectasis, or more commonly some combination of both these conditions. Such gross lesions as follow the textbook account under these headings are readily recognized and need no recapitulation. What I would here emphasize is the common occurrence of slighter degrees of damage, readily overlooked, but often the explanation of anomalous signs and symptoms at some later period. Mistaken as a rule for pulmonary tubercle, they present a ready pitfall, unless recognized, in the realms of diagnosis, prognosis, and also of therapy, for they are very amenable to well directed treatment. "Damaged lung" is the somewhat loose term that best covers, to my mind, the varied mixture of mild fibrosis and dilated bronchial tubes with which I am here dealing, but it is, of course, the bronchiectasis that counts—or rather "bronchiolectasis," for it is the small tubes which are generally implicated in these cases. It will be most convenient to consider the subject under separate headings in children and in adults, but it is in the early years of life that the majority of all cases originate.

*In Childhood.*

Many years ago I collected some 40 cases of pulmonary fibrosis and bronchiectasis in childhood for purposes of study and analysis. These, which included slighter cases of similar etiology, showed clearly the common origin of lung damage from the inflammatory lung diseases of childhood, particularly in association with the infective catarrhs of measles and whooping-cough. It is interesting in this connexion that American investigators have recently associated a definite thickening of x ray lung shadows after these two diseases. But bronchopneumonia stands out in childhood as the prime causation of lung damage, and this is found clinically at the bases of both lower lobes.

Bronchopneumonia—						Cases.
Simple	...	...	...	...	...	6
With whooping-cough...	...	...	...	...	...	5
With measles	...	...	...	...	...	3
						—14
Bronchitis—

With whooping-cough...	...	...	...	...	...	3
With diphtheria	...	...	...	...	...	2
With measles and whooping-cough	...	...	...	...	...	2
						—13
Lobar pneumonia	...	...	...	...	...	4
Congenital atelectasis	...	...	...	...	...	2
						33

To these I should add, with further experience, two other causes in childhood—influenzal pneumonia and tuberculosis. Influenzal pneumonia leads very readily, as in adults, to fibrosis and bronchiectasis, and I have seen several cases which well illustrate this fact. The lung damage left after tuberculosis in early childhood will be an object of scepticism to many who still hold desperate views as to the mortality of the disease at this age period. The x rays have long convinced me of the recoverability of pulmonary tuberculosis even in infancy, and in such cases some signs of lung damage generally remain behind.

Let us now consider some common types of "damaged lung" in childhood.

First, there is the case in which the condition may be seen to develop after bronchopneumonia. The signs at the bases of the lungs, percussion impairment, and crepitations do not completely clear up after the child appears otherwise well and vigorous. A not uncommon sequel is a further attack, which may appear to be bronchopneumonia, but is somewhat milder than the original attack or than the usual course (very varied, by the way) of this affection. Sometimes repeated attacks supervene, and it is always wise when a case of bronchopneumonia is seen for the first time to inquire for former similar illness. A history of this, the mild course of

the illness in some cases, occasionally a slight clubbing of the nails also, may help us to suspect that an attack is occurring on the top of lungs already "damaged." These further attacks may amount to a mere acute catarrh of the dilated bronchioles, with some "congestion" of the surrounding lung, but no true pneumonic consolidation. In other cases a fresh bronchopneumonia occurs; the physical signs are very similar in both cases.

The second commonest simulation of "damaged lungs" in childhood is of pulmonary tuberculosis. Most of the cases are basal, and then the mistake is less likely to arise; but when a coughing child presents an area of impairment and crepitations at an apex, commonly the right, it is no wonder if he gets treatment for pulmonary tuberculosis sometimes for years on end. Only recently two such cases, which had been under prolonged treatment, were sent to me by a tuberculosis officer in the London district for comment and discussion. Such cases originate, I think, in apical lobar pneumonia, the right apex being the second commonest situation of the lesion in this disease in childhood (the left base being the commonest). The children are much less ill (often not ill at all) than they would be with tuberculous lesions of similar extent, and the history and course, if other points fail, should suffice to make clear their nature. The physical signs of a "damaged lung" in childhood necessarily vary with the case. Where there is much fibrosis this is indicated by marked dullness, feeble breath sounds, often with diminution of vocal vibration, and by contraction of the diseased area. Where bronchiectasis involves the larger bronchi, no added sounds may be audible or a few coarse râles are heard. It is where the smaller bronchial tubes, and these near the surface, are affected that the more typical signs—breezy consonating crepitations, sounding very superficial—are heard. In many cases these sounds may simulate pleural friction. Typically, as occurring after a protracted bronchopneumonia, they closely simulate, both in nature and in distribution, the physical signs found in this disease—the symptoms of illness disappear but the signs remain! When a lung from such a case can be viewed on the *post-mortem* table it shows a reticulated appearance from the development of numerous bronchiolar sacs.

Now the failure of bronchopneumonic signs to clear is no uncommon occurrence; many such cases of bronchiolectasis leave our children's hospitals, and it may well be asked what becomes of them. Some may, perhaps, be still recoverable; some, we have seen, return with recrudescences of catarrh; but there are others whose health does not appear to be prejudiced but who yet retain some damage to their lung bases and carry this presumably into adult life—where we shall meet them again farther on in this paper.

As to the symptoms of "damaged lungs" in children, these will depend on the amount and nature of the bronchiectasis. Some will have cough and nothing to show for it; others will bring up sputum, and occasionally blood, in varying quantities. But few appear to be really ill or toxic in their early years, apart from the severe febrile lung attacks to which a proportion of them are prone. The sallow skin, with wasting and foul sputum characteristic of bad cases of adult bronchiectasis, are much less common in childhood.

*In Adult Life.*

"Damaged lungs" in adult life are very commonly the inheritance of inflammatory diseases in childhood. Not to speak of marked and typical cases, we may meet with the conditions to which I would draw attention under very different circumstances.

First, there are cases where a "basal bronchitis," strictly confined to the broncho-pneumonic area, is found—generally as a chronic condition with exacerbations. My belief that these are cases of bronchiolectasis derived from a childhood bronchopneumonia is a mere pious opinion. I have no real proof to offer. May not they represent a proportion of those cases of unresolved bronchopneumonias which retained their damage with but little immediate ill health? The history of certain of them suggests that this is so. More likely still is this the case in many cases of so-called bronchopneumonia, apart from influenza, in adults. Influenzal bronchopneumonia must of course be given its due place, but I am myself doubtful of most of the so-called bronchopneumonias of other causation in adult life. In many such cases the signs and symptoms are much more suggestive of a severe catarrh in an old basal bronchiolectasis, and in such cases the signs will not completely clear up after the attack. They may, however, be slight and easily overlooked in the quiescent state,

where the dilated tubes are not close to the surface (this is illustrated by experience of less debatable cases in childhood). If a careful history of such a case is taken, with the assistance of an elder relative, a clear record of bronchopneumonia, sometimes repeated, in early life is not infrequently obtained.

It has already been mentioned in dealing with bronchiectasis in childhood that blood is not infrequently coughed up, and that, occasionally, in notable amount. This may occur in adult life also, and I have known it to occur in a patient who had lost all recollection of former chest disease, but who presented a well marked basal bronchiectasis, of which his female relatives were able to supply a perfectly clear account from his early childhood. The case was, of course, under dire suspicion of pulmonary tubercle.

In addition to damage from childhood infections, the lungs of adults are also very apt to suffer scarring from the results of recovered influenzal pneumonia and of tuberculosis. Basal bronchiectasis or bronchiolectasis, not infrequently double, is not uncommonly to be seen since the recent epidemics. Sometimes it gets forgotten until some acute exacerbation brings it once more to the notice of the medical attendant. Occasionally it has been so far overlooked that some fresh disease, generally tuberculosis, comes under suspicion when new symptoms arise.

The lung damage caused by the healing of tuberculous lesions is so large and varied a subject that I shall not attempt to touch more than one aspect of it here. I would only urge that some amount of bronchiectasis is the usual accompaniment of chronic tuberculous lung disease. The point I wish to call attention to is the presence of crepitations over the diseased areas in cases of arrested or healed pulmonary tuberculosis. Such an occurrence is not uncommon, and yet one finds but little reference to it in the literature. I have many cases under observation which have been long arrested, but where crepitations remain, and might cause anxiety in the mind of an uninitiated observer. In some of these cases there are but the dry crackles of expanding lung, but in others the crepitations are somewhat moist and are due, I feel sure, to dilated bronchioles over a contracting fibroid area—generally in the region of a deep contracting cavity. The diagnosis of "arrest" may be difficult where these are present—it is greatly helped, in my experience, by the absence, in these cases, of the "reflex bands of percussion impairment" which I have described elsewhere on more than one occasion.

In conclusion, I should like to insist on the point, which perhaps I have hitherto only implied, that fibrosis and bronchiectasis, and "damaged lung" in general, vary according to the severity of the inflammation which produced the condition. It is attention to the slighter grades for which I here plead—the textbook account of bronchiectasis applies to the few marked and uncommon cases, whereas the slighter forms are not rare and are seen at all ages. They do not provide us with "pints of fetid sputum which separates into three layers," but they provide us with a varying symptomatology, and with problems in diagnosis, prognosis, and treatment, which may be of vital importance to our patients, and not without moment to our own *amour propre*, and, incidentally, our reputation.

## AN UNUSUAL CASE OF TYPHOID SPINE WITH SYMPTOMS OF SPINAL CORD AFFECTION.

BY

PROFESSOR H. TURNER,

ORTHOPAEDIC CLINIC OF THE MILITARY ACADEMY OF MEDICINE,  
PETROGRAD.

NUMEROUS clinical observations and pathological research of past years have brought convincing evidence of the fact that the infective agent of so-called acute internal disease may settle on different parts of the skeleton, bringing injuries to bone, cartilage, or component parts of the joints (Virchow, Rokitsansky, Ponfick). It is well known that even such exclusively internal diseases as influenza may involve the osseous tissue. The "amphibious" qualities of the pneumococcus are proved by every day's observation. Its nefarious rôle in the production of osteomyelitis and arthritis has been very often the cause of diagnostic errors. The ranks of specific "surgical"

microbes, as primarily defined by Ogston, W. Cheyne, Rosenbach, and others, have been gradually enlarged by the enlistment of many other pathogenic elements, which have come forward from the domain of acute infectious diseases such as those belonging to the multifarious group of typhus—that is, typhoid, recurrent, and typhus (spotted) fever. The widespread epidemic of these latter diseases, observed in Russia during recent years has given birth to vast material concerning this subject, and Russian literature, notwithstanding its internal difficulties, has been able to bring to light many of the surgical complications of typhus fever in general. Typhoid or enteric fever, with its stubborn bacteria, capable of retaining vitality in the organism for many years after the conclusion of morbid symptoms, stood foremost in this relation, although recurrent and spotted fever did not remain much behind in showing the same quality. Clinical observations on a large scale gave us the opportunity of confirming the findings of Ebermeyer, Fränkel, Quincke, and many others, who discovered typhoid bacilli in the vertebrae, ribs, sternum, and other bones of the dead body.

The special tendency of the spine to become the seat of infection, as explained by Fränkel's demonstrations of living typhoid bacilli in the cancellous tissue of the vertebral body, we have seen represented in the numerous cases of typhoid spine which came under our observation in the orthopaedic hospital of the Medical Academy. Experience has taught us to mark off these forms of spondylitis amidst the greater number of tuberculous cases, and generally there was not much difficulty in avoiding errors of diagnosis.

The involvement of the spine in the typhoid process takes place, with great probability, during the flourishing period of the disease, and must be of not very rare occurrence. The symptoms of this complication may pass unremarked on the background of the grave picture of the illness. A new wave of temperature, accompanied by severe pains in the back, may draw attention to the intrusion of the virus into the spine. The further progress of the complication may be very slow, not taking a malignant course. It seems as if bone tissue, especially the cancellous part of it, is not a suitable pasture for the typhoid microbe, the feeble pyogenic and destructive character of which has been proved by many communications. The symptoms of the infection may in some cases subside without having been clearly understood, natural curative forces having extinguished its continuance. But as in other parts of the body, and especially in the intestinal channel, the virus of typhoid fever, secluded in the vertebrae, may retain its vitality for months and years, only to regain force under convenient circumstances, trauma in any form being the auxiliary agent.

It may be stated that the pathological anatomy of typhoid spine in the different stages of its development is not founded on such abundant data as in the case of Pott's disease. The benign course of typhoid spondylitis allows the patients to evade further clinical observation, and the final changes in the vertebrae have to be studied on occasional findings in the anatomical theatre or on the shelves of museums. The examination of these specimens, and the interpretation of the pathological changes presented by them, are hampered by the want of clinical notes. It is not easy, therefore, to define clearly the type of typhoid or other infectious spondylitis among the multifarious pathological processes to which the spine is so conspicuously liable. Roentgen rays have done very much to help our advance in this difficult field. The findings seen on the plate, elucidating the origin of clinical symptoms, present themselves as useful guides in the examination of dry pathological specimens. Taking this course of study, I have been able to discern with a great degree of positiveness the doubtful cases of infectious spondylitis compiled by me in the surgical museum attached to my clinic. The general impression received from the examination tends to confirm the supposition that the process of typhoid spondylitis is actually a form of subacute inflammation involving the periosteum, ligaments, and vertebral articulations. Gibney's term, "perispondylitis," remains the most suitable for a brief determination of the pathological changes. The posterior lateral parts of the laminae are principally involved, their mobility probably influencing the exacerbation of the process.

This point of view may help to explain the frequent localization of the illness in the lower dorsal and upper lumbar regions. Ossification of the tissues adjacent to the bone brings firm consolidation of the laminae and locking of the joints. The massive layers of newly formed bone on the

outer surface of the posterior wall of the spinal channel are sometimes exceedingly imposing. Continuous or interrupted bridges are to be seen between the vertebral bodies. The intervertebral discs seem to undergo a process of atrophy, the intervals between the adjacent surfaces of the bodies becoming narrower. In some cases there is to be seen complete synostosis of laminae, articulations, and bodies. Two or more vertebral bodies become firmly and inseparably united. One of my specimens coming from a juvenile subject clearly represents the result. The vertebrae have been united in three pairs, beginning from the lower lumbar and ending by the twelfth dorsal. The next three dorsal vertebrae (9-11) are also firmly glued together, showing traces of heavy destruction of the bodies. And yet there is no kyphotic curve of the spinal process line. The fact of the vertebral bodies having been impaired in this case emphasizes the common assumption that the anterior cancellous part of the column may not be exempt from the destruction. It seems to confirm the investigations of E. Fränkel, who was able to cultivate typhoid bacilli procured from bone marrow squeezed out of the spongy tissue of the vertebrae after death. The paradoxical absence of kyphosis in such cases is easily explained by the effect of previous ankylosing periostitis binding together the posterior halves of the laminae and locking the articulations. The same interpretation may be accepted for the rare occurrence of grave spinal cord symptoms in typhoid affections; paralysis from cord compression is not spoken of.

The picture of typhoid spondylitis as represented by the Roentgen plates is very characteristic. Attention is drawn to the narrowing or partial disappearance of the intervertebral spaces and to the lateral protrusion of the contiguous edges of the bodies. Dense vertical shades on one or both sides of the middle line reproduce the massive bridges of newly formed bone by which the posterior parts of the column are soldered together. A scoliotic curve may be occasionally seen as the result of asymmetrical disposition of the disease.

As regards the clinical symptoms of infectious spondylitis, it may be said that they differ very much from those in Pott's disease. Acute excruciating pain in the back is the chief complaint. Every least movement exaggerates the sufferings; the undulations of a spring mattress may bring them on. The exact situation of the process may be easily determined by manual examination, although kyphotic projection may be absent. Digital pressure reveals intense pain in the lateral parts of the spine. The soft coverings of the region involved may be thickened and oedematous. In some cases several foci of the disease are to be found in different levels of the spine. Fever of an intermittent type generally accompanies the process in its initial stage. Tendency to suppuration or the formation of fistulae is very rarely observed, the diagnosis thereby being deprived of bacteriological proof. According to our clinical experience and the bacteriological findings of Quincke, E. Fränkel, and others, one must allow the assumption that the involvement of the spine in the typhoid process is a frequent integral part of the disease as a whole, the infection continuing to exist in a latent state. The awakening of the process is generally brought about by trauma, be it in the form of an early attempt to leave the bed or to resume physical work. Therein lies the explanation of the development of typhoid spondylitis some months or even years after recovery from the initial disease. The symptoms and clinical course of spondylitis produced by spotted or recurrent fever are similar to those above described.

The following case may be offered as an interesting addition to the general statistics of the subject:

L. M., aged 23, Red Army, infantry, admitted to the orthopaedic department May 21st, 1921. In November, 1919, he developed typhoid. In February, 1920, he began to suffer from pains in the back. Having re-entered service on August 12th after two months' leave he continued feeling the same pains. In December, 1920, he went through an attack of recurrent fever. Called up again soon after, he began to lose power in his legs in March, 1921. After a certain term of treatment in a military hospital he came under my care.

On admission his state was as follows: General health good. Robust complexion. Standing or walking absolutely impossible. Distinct signs of partial spinal cord compression in the form of a hile and patella clonus; Babinski's phenomenon; rigidity of muscles and weakness of the lower limbs; loss of muscular feeling in the toes; skin hyperaesthesia to pain on the level of the seventh to eighth dorsal segments, and hyperaesthesia to all kinds of sensation on lower down. State of atactic paresis of the lower limbs. No trouble of the bladder or rectum. Examination of the spine shows a not clearly defined swelling between the shoulder blades corresponding to the fifth to seventh spinous processes. The integu-

ments of the same region oedematous and reddened. Fluctuation distinct. Palpation of the diseased area of the spine inflicts great pain, especially in the lateral parts of the vertebrae. Vidal's reaction of the blood positive. Temperature between 38° and 39° C.

Patient complains of great pain in the back, especially with every movement. On opening the abscess under general anaesthesia, on May 25th, slightly odorous grey-green pus was found, from which a pure culture of typhoid bacilli was obtained in the bacteriological laboratory of the Academy. There was no doubt about the identification of the micro-organism, as it showed all the usual tests. The cavity of the abscess was found to be located to the right of the spinous processes, leading deeply towards the corresponding laminae. No denuded bone could be felt during the scooping out of its contents.

The subsequent course of the case long duration, spinal cord symptoms fistula, periodically closing and reopening containing the specific bacteria. Voluntary movements of the legs reappeared in July. The hyperaesthesia disappeared. Babinski's sign and clonus still persisted. By December, 1921, the patient was able to walk freely. At times he felt acute pains in the region of the operation. A probe periodically introduced into the fistula met with something hard resembling denuded bone. The attempts to extract the "sequestrum" were futile, although it seemed to be movable. On June 2nd chloroform was administered and the fistula cut open. With a strong forceps I extracted a foreign body, which proved to be the middle part of a penknife blade about 1 cm. square, thus astonishing my staff and myself. The patient being eager, still in a drowsy condition, to see the obnoxious bone which had troubled him for so long, the piece of metal was shown to him. His look seemed to wander as if trying to recollect some distant event. "Yes," said he, after a pause, "there has been an affair." The details of the adventure were obtained on the next morning. In the winter of 1918, before he entered service, he took part in a sleigh trip in company of his equa's containing representatives of his parish. Having the advantage of being able to play the harmonica, he was stabbed from behind by a jealous village comrade. The blade of the penknife broke into pieces on striking the vertebral laminae; its point probably penetrated the cortical layer of the bone and broke off. The small wound healed without any further trouble in a few days, and no subsequent attention was paid to the tragic event.

In need of a justification of my publishing the above case, I may point to the fact that it is the only positive one, according to my knowledge, in which typhoid spondylitis was complicated by suppuration. The bacteriological verification of the origin of the disease is also of singular interest. The previous trauma, which may have stimulated the onset of the suppuration, is also to be underlined. Symptoms of cord affection are a not very frequent concomitant in typhoid spondylitis.

The wound having healed in two weeks, the patient walked out of the clinic on June 29th, 1922, with some traces of nervous disorder in his legs.

## TREATMENT BY DIATHERMY.\*

BY

W. J. TURRELL, M.A., M.D. OXON.,

ELECTROTHERAPEUTIC PHYSICIAN, RADCLIFFE INFIRMARY, OXFORD.

THE title of this communication does not necessarily imply the adoption of any electrical method. It simply refers to treatment by penetrating heat. The subject consequently admits of division into two parts: (1) the therapeutic effects of heat penetration; (2) the most effective method of securing this penetration, having due regard to its safety, the ease of its regulation, and its capability of application to the body as a whole or any organ or part of the body.

As to the first part there can, I think, be no difference of opinion in regard to the great importance of heat as a therapeutic agent. Its value has, in fact, been admitted from the earliest times to which medical history extends, and probably no method of therapy has been more unquestionably or more universally adopted.

A variety of methods have been utilized for applying heat treatment—hot sand, hot bricks, poultices, radiant-heat baths, sun baths, paraffin baths, and many others too numerous to mention; but the therapeutic value of all these methods is distinctly and definitely limited, for the simple reason that their action is restricted to the surface of the body and the superficial tissues, and cannot be brought to bear directly upon the deeper organs and structures. They are consequently useless as agents for treatment by diathermy or heat penetration.

There is only one known method by which heat can be

\* A paper read at the annual meeting of the Oxford and Reading Branch of the British Medical Association, July 13th, 1922.

directly applied throughout the body as a whole or concentrated on any limb, on any organ or part of the body, and this is by the electrical method commonly known as diathermy, the outcome of the research of the distinguished French physicist d'Arsonval.

#### Mode of Action.

This fact well illustrates a very important point in relation to electrical treatment. In the past electrotherapy has been regarded by many patients, and, indeed, by some medical men, as an empirical and mysterious form of treatment passing all human understanding. In reality it is nothing of the kind; its value, on the contrary, rests upon the fact that it is often the best means by which some well established method of treatment can be carried out; as in the present instance, it is the most effective method of administering heat; in other cases it is the best method of producing muscular exercise, localized or general; or again, it may be the best means of effecting chemical or other changes in the tissues. I will endeavour, as simply and as briefly as I can, to explain in what manner this heat penetration is electrically obtained.

An electrical current may be in the form of what is termed a constant current—that is to say, a current which is maintained at a uniform strength, flowing in the same direction without interruption, reversal, or variation; such is the direct current, the D.C. of commerce. Or, on the other hand, it may be interrupted and its direction reversed at each interruption, as in the alternating current, the A.C. of commerce, with its usual periodicity of about fifty reversals a second.

Provided that the constant current is applied to the body very gradually no muscular contraction will be excited, but during the whole of its passage an acid such as HCl will be formed on the skin at the positive pole by what is termed electrolytic action, and an alkali such as caustic soda will be similarly formed at the negative pole. With the small constant currents usually applied in electrotherapy these phenomena will produce no bad results; but if a very strong current is applied these products will cause serious burns of the skin or subcutaneous tissues; the amount of current which can be safely applied is therefore insufficient to produce any very marked heating effects.

On the other hand, in the case of the alternating current, changing its polarity from positive to negative fifty times a second, the danger of such burning is absent as the alternating products neutralize one another. But at each sudden make or reversal of the current strong and painful muscular contractions are excited, and if a very strong current was employed the effects might even result in the death of the patient.

In 1888 d'Arsonval found that by increasing the number of the interruptions a second of a current at a given strength, the resulting contractions became more vigorous as the interruptions became more frequent; until a rate of interruption of from 2,500 to 5,000 a second was reached, when a further increase in the frequency resulted in a diminished vigour of the contractions. In December, 1895, using the apparatus of Hertz, d'Arsonval attained a frequency of interruption or oscillation of about a million a second, with the result that all contractions and sensation were abolished, and only the heat generated by the friction resulting from the oscillation of the electrical particles (the ions converging the current) remained. This constituted the discovery of high-frequency currents, and by subsequent improvements in the apparatus the frequency of the oscillations was further increased, yielding the diathermic currents of d'Arsonval.

I will merely state that in its main principles the apparatus is identical with the transmitting apparatus of wireless telegraphy, and it admits of the passage through the body with perfect safety of currents of 2 or 3 ampères—that is to say, a hundred times or more stronger than could be transmitted by the continuous or alternating currents. The only effect of the transmission of such currents through the body, apart from a probable stimulation of the tissue cells due to the perturbation excited by these oscillations, is the generation of heat of any desired amount within any organ of the body. According to the density of the diathermy current employed, this method of heat penetration may be utilized for either medical or surgical purposes.

When a diathermy current of moderate intensity is applied transversely through large areas of the body, or longitudinally through the limbs, the temperature of the body at first rises to about one degree above normal, and the pulse becomes accelerated about 10 beats a minute; then, as the heat-regulating centres come into play, the pulse becomes softer and fuller, the temperature returns to normal and will remain normal for the rest of the treatment, although it may be continued for an hour or more at the same intensity. By passing very large currents such as 17 ampères and over through the body a marked rise of the general temperature can be obtained, and if such currents are continuously administered for a considerable time, as has been done in experiments on animals, the action of the heat-regulating centres will be overcome, and the animals will die of hyperpyrexia.

A very small current, such as 300 ma., does not appear to call the heat-regulating centres into action to a relatively marked

extent, and consequently with small currents a relatively greater heating effect may be obtained. Thus it has been shown that on heating the stomach by a diathermy current of 300 ma. the temperature of that organ was raised to half a degree above normal, but, on increasing the current to ten times that strength, the temperature of that organ fell to only one-third of a degree above normal.

#### Medical Applications.

The importance of these experiments is that they show the immediate and consecutive effects of diathermy. The first effect is to raise the temperature of the part treated; the later effects are a relaxation of the tissues, a dilatation of the blood vessels, and consequently an increased blood supply to the part treated. In this way the therapeutic effects of diathermy are explained—namely, the lowering of the blood pressure, the relaxation of spasm with the relief of pain, and an improved nutrition of parts whose blood supply has been deficient.

Without attempting to formulate any new theory of pain, I should like to recall the intimate and causal relationship which exists between pressure and pain; it is by relieving spasm and pressure, and hence removing pain, that diathermy finds one of its most important indications in clinical practice. Neuritis, deep-seated pain such as that associated with dysmenorrhoea or the spasm of a ureter excited by the passage of a calculus, the hypertonicity of the lumbar muscles in lumbago or the neck muscles in torticollis, the muscular rigidity of local tetanus, the pain and tenderness of a recently strained ankle, and many other conditions too numerous to enumerate, are usually markedly relieved and often permanently cured by the application of this treatment.

The nutritional effect of the increased blood supply induced by diathermy is constantly seen in the improvement which takes place in wasted limbs and atrophic conditions treated by this method.

Hypothermic and marasmic conditions are much relieved and improved by generalized diathermy. Bergonié has advanced the ingenious theory that its administration in these cases affords what he terms a "supplementary ration of heat"—that is to say, he maintains that, as the greater part of the food taken is diverted to the maintenance of the body temperature, if heat is furnished to the body by diathermy the food previously diverted for this purpose would be utilized for the nourishment and building up of the tissues. Bergonié further points out that the custom of giving additional food, owing to the weakened digestive mechanism associated with these marasmic cases, merely serves to add to the troubles of indigestion to those already existing. Bergonié has published several cases in proof of his contention; moreover, the theory would appear to receive some support from the improved nutrition of rickety children exposed to the prolonged action of the sun bath; for such improvement may be partly due to the gradual action of the heat rays from the sun and partly due to the action of its actinic rays.

When we realize the very wide application of heat therapy it is not surprising to find that diathermy is continually extending its sphere of action. To mention only a few of the recently adopted indications, Professor Bordier, in the excellent and exhaustive volume on diathermy which he has recently published, draws attention to the great benefits attending the adoption of this treatment in certain cases of dyspepsia, and quotes a number of cases investigated by Setzu to show how it increases both the total gastric output of acids and of free hydrochloric acid. Setzu's carefully investigated cases definitely show how the secretion of a deeply seated organ may be increased by the administration of penetrating heat, and suggest a wide field for research on the effect of diathermy on ductless glands whose secretion has become deficient.

The special vulnerability of gonococci to high temperatures renders possible their destruction, or an impairment of their vitality, at temperatures obtainable from diathermy and their readily supportable by the tissues, and thus renders this treatment a specific in gonorrhoea and most of its complications. Many other conditions, such as asthma and uresorel pneumonia consolidation, will suggest themselves as especially suitable for gradual and prolonged diathermic treatment at low intensities, but time forbids me to deal further with the medical aspects of diathermy and I must pass on to its surgical side.

#### Surgical Applications.

In surgical diathermy the heat, which in the medical applications is distributed over a comparatively large area, is concentrated on one spot. It differs from the destruction of tissue by heated irons or the Paquelin cautery in that

when properly applied it effects the destruction by heat coagulation and not by charring or incineration.

Those who have used the Paquin cautery will remember how the charred tissues adhere to the blade of the instrument and become separated from the heated surface of the part treated, so laying open a bleeding surface. In surgical diathermy the instrument utilized is not itself heated; the whole of the heat being developed in the part treated; it consequently does not adhere to the tissues but comes cleanly away, leaving them undisturbed but firmly coagulated to a sufficient depth to prevent haemorrhage.

It is not claimed that surgical diathermy is an absolutely fool-proof method, for if it is applied incautiously in the neighbourhood of large vessels the wall of an imperfectly coagulated vessel may be laid open and fatal haemorrhage ensue. Such an occurrence has been recorded by Bordier and others in the destruction of malignant tonsils by diathermy. The risk of haemorrhage from surgical diathermy, if it is applied in a rational manner and with due regard to the anatomical relations of the part treated, is exceedingly small.

The methods of its application are threefold: the unipolar method, utilizing a small active and a large indifferent electrode; the bipolar method, using two small active electrodes; the indirect method, in which the patient, lying on a condenser couch attached to one terminal of the apparatus, and holding an electrode connected with the other terminal, is charged with a suitable diathermic current, which is tapped off to the body of the operator at the point to be destroyed.

For the destruction of most superficial growths, sufficiently removed from important underlying structures, such as large blood vessels, nerves, glandular ducts, etc., the unipolar method is usually the most convenient one. It is, however, difficult with this method definitely and accurately to restrict the depth to which the coagulating action of the heat will extend, and in the neighbourhood of important structures it is best to delimit the destructive action of the current by the adoption of the bipolar method. In this case two small active electrodes of the same size are applied to the surface of the part to be treated, and the destructive action is limited to a slight and readily recognized depth. The destructive action may, however, be still more effectively controlled by the use of electrodes provided with multiple points of the required length. These electrodes consist of small plates, from the under surface of which several needles project; by plunging each of the instruments, at a suitable distance from one another, into the growth to be destroyed, the action of the current reaches with certainty to the desired depth, and cannot extend more deeply.

The indirect method, which I introduced some years ago, is especially suitable for the treatment of small growths, naevi, papillomata, warts, urethral caruncles, epulides, etc. The advantages are that it is the most accurate method and the least painful; the instrument held by the operator is unencumbered with any wires, and as the amount of the current employed is registered by the ammeter of the apparatus before the treatment is started, the amount of current can be suitably adjusted

before the operation is commenced. If with the patient charge in the manner described a papilloma or other growth with a narrow pedicle be held by the operator by means of metal forceps, the narrow base of the pedicle will coagulate and the growth will painlessly separate.

Intra-vesical growths, haemorrhoids, superficial growths, malignant or otherwise, on the surface or within accessible cavities, lupus, moles, enlarged tonsils, naevi, and many other conditions are suitable for surgical diathermy; it is also a most delicate and efficient means of epilation. Speaking from my own experience, my greatest success with surgical diathermy has been in the treatment of haemorrhoids. Intra-vesical growths are best treated by a surgeon specializing in diseases of the bladder, as the cystoscope is a far more difficult instrument to use than the diathermy instruments; in fact, I am of opinion that all the more severe diathermy operations, such as the destruction of large malignant growths, belong rather to the surgeon than to the electro-therapist.

#### Concluding Remarks.

I have endeavoured to give a brief summary of the therapeutic action of diathermy. It is, of course, impossible to deal adequately with so large and important a subject in so brief a time; indeed, we have by no means as yet fully developed the therapeutic possibilities of heat penetration by electrical means. As Bergonié points out in his introduction to Bordier's book on diathermy, the end of the last and the beginning of the present century have given us the high-frequency currents of d'Arsonval, the x rays of Röntgen, the radium emanation of Becquerel and the Curies; but the period which has as yet elapsed since their introduction has proved insufficient to enable us to develop fully their methods of application or even to visualize fully their wide reaching and revolutionary effects.

Every new discovery in Medicine, whether electrical, pharmaceutical, or surgical, is invariably heralded as an era, and from its application miraculous results are predicted, which the lapse of time fails to justify. In the past, as Bergonié says, seen every illusion flourish and have heard every physical panacea preached. It is only by patiently and critically investigating the clinical action of these new methods and by carefully tracing out their fundamental basis that we are able to establish them upon a sure and lasting foundation. Working upon such lines as these, the modern school of electro-therapists, both in this country and abroad, may fairly claim to have placed the high-frequency currents of d'Arsonval upon the firm and far-extending foundation of heat penetration, and upon this basis to have secured for them an important and enduring position among the therapeutic methods of the future.

### The FitzPatrick Lectures

ON

## THE POST-HIPPOCRATIC SCHOOLS OF MEDICINE.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS OF LONDON,

BY

R. O. MOON, M.D., F.R.C.P.

[Abstract.]

In my lectures in 1921 I endeavoured to show how Hippocrates had been influenced by the great Ionian philosophers who had preceded or been contemporary with him, and by the scientific and general intellectual atmosphere in which his writings had been composed.

Just as after the death of Socrates the essential unity of his teaching broke into a variety of schools—such as the Cynics, Cyrenaics, Megarians, and, in particular, the followers of Plato—so after the death of Hippocrates, medicine became split up into a number of sects, each at its best emphasizing some important aspect of medical truth, but each in turn, as is the habit of all sectarianism, running into strange extremes, and remaining incapable of grasping the Hippocratic system as a whole.

The post-Hippocratic schools of medicine, which were four in number—(1) the Dogmatists, (2) the Empirics, (3) the Methodists, (4) the Pneumatists—occupy perhaps a somewhat unimportant sphere in the history of medicine, but the great

philosophic schools of the Stoics, Epicureans, Sceptics, and Eclectics which influenced them, and of which, in a sense, they were the practical outcome, are famous through all time, and some attempt will be made to describe them when trying to explain their points of contact with medicine.

#### THE DOGMATISTS.

The school of the Dogmatists in its prime synchronized with the decline of Hellenic freedom and with the rise of the Macedonian hegemony. This school received its name from Galen, and, though not very happily chosen, it must be retained for convenience. If we were to call them "theorists" we should come nearer to the essential idea which they represented in the ancient world. To the modern mind dogmatism is suggestive of a certain degree of intellectual rigidity and aridity which were certainly not characteristics of this ancient medical school. But they suffered from what Bacon called that first distemper of learning, when men study words and not matter.

The most important member of this school, though not the actual founder of it, was Diocles of Carystus, who flourished soon after the death of Hippocrates. He was born at Carystus in Euboea (400 B.C.). The greater part of his life was passed at Athens, and with pride he was termed by his fellow citizens "a second Hippocrates." He was the first physician to write in Attic Greek, and his writings covered the whole field of medicine—namely, Physiology, Anatomy, Dietetics, Pharmacy, Pathology, Therapeutics, and Prognosis. He was first to isolate pleurisy from pneumonia, declaring that the seat of pneumonia was in the vessels of the lungs.

Speaking generally, in his dietetic writings Diocles adopted

the Hippocratic point of view, and laid down most minute directions for every hour of the day—for the morning walk, for sleeping, for working, for cleaning the teeth, and so forth. But the bond which specially united Diocles with Hippocrates was his recognition of the fundamental teaching of the great physician that it is impossible to understand the nature of the body without knowledge of the Macrocosm, which is so well exemplified in the Hippocratic treatise of airs, waters, and places. In the writings of Diocles, as in those of Hippocrates, we find an effort to bestow a continuous consideration on the climate, seasons, surroundings, and also the life habits of the sick.

Another distinguished member of the school of Dogmatists some sixty years later was Praxagoras of Cos. He was the son of Nicharchus and the teacher of Herophilus, also he was the father of the celebrated poet Theocritus, and the pupil of Diocles. It appears that Praxagoras was the first to discriminate between the arteries and the veins, and to use them for his teaching on the pulse, to which he attached the greatest importance, saying that the pulse in diseased conditions indicates the changes of the vital force. All mental diseases, he thought, originated in the heart; according to him epilepsy was caused by the destruction of the arteries through excess of phlegm. The nerves he seemed to have looked upon as the organs of sensation, but did not distinguish them entirely from the vessels and tendons; their origin he believed to be in the heart—doubtless because Plato had made the heart the seat of sensation. Unfortunately, he confused himself by taking the terminal branches of the arteries for nerves.

The school of the Dogmatists had a peculiar method of treating fever: first they caused a patient suffering from fever to be covered with a large number of clothes in order to produce heat and thirst; as the fever remitted the patient was given cold water to drink with a view to producing a sweat. If this did not come about the patient had to drink salt water, and this caused vomiting. When by one of these methods the fever was brought to an end, the patient was given roast pork and allowed to drink as much wine as he liked.

But the most distinguishing characteristic of the Dogmatists was that they had taken as their guiding motto the saying of Hippocrates that "the physician who is also a philosopher is godlike," and with commendable zeal they proceeded to earn this title by a careful study of the *Timæus*—the only dialogue in which Plato gives a concise explanation of his notion of the physical world and puts forward some definite anatomical and physiological ideas; but such subjects, we must realize, were certainly not of primary interest to Plato, who was far more concerned with metaphysics and the nature of ultimate Being, and so the dialogue is put into the mouth of a Pythagorean and not of Socrates, who also stood aloof from physical speculation, which in the *Phædo* he said he had renounced. Plato himself did not attribute any importance to his own guesses at science. He is not absorbed by them as he is by "the Idea of the Good," for he regarded speculation on physics as a rational pastime only. He would have thought it an impiety to rank physics first in the order of knowledge, as that would mean placing the body before the soul. In the dialogue of the *Timæus* there is much derived from Plato's theory of the universe and applied to man, as there is much in his theory of the universe which is suggested by man. The microcosm of the human body is the lesser image of the macrocosm; the animal, he imagined, acted as a sort of world to the particles of blood which circulate in it. Like Hippocrates, he believed in the *vis medicatrix naturæ*, and seems to have thought that physicians were more or less useless; we know that they as well as lawyers were banished from his ideal republic.

Now in trying to form an estimate of the science of the ancient world it is difficult to realize how great a thing it was to have framed a conception, however imperfect it might be, either of the human body as a whole or of the world as a whole. It is very doubtful whether the Egyptians or Babylonians ever formed such conceptions. General notions are notions which are necessary for the discovery of particular facts, the metaphysical for the physical. Before men can observe the world with any profit they must be able to conceive the world—the string is wanted no less than the individual pearls.

There is a passage in the *Laws* of Plato in which he described two kinds of doctors, and in the superior kind, who are the doctors of freemen, we can easily recognize the

prototype of the Dogmatist physician. The passage is as follows:

"And did you ever observe that there are two classes of patients in States, slaves and freemen? And the slave doctors run about and come to slaves and wait for them in the dispensaries—practitioners of this sort never talk to their patients individually, or let them talk about their own complaint; the doctor prescribes what he thinks good out of the abundance of his experience, as if he had no manner of doubt, and when he has given his orders, like a tyrant, he rushes off with equal assurance to some other servant who is ill, and so he relieves the master of the house of the care of his invalid slaves. But the other doctor who is a freeman attends and practises upon freemen, and he carries his inquiries far back and goes into the nature of the disorder [this, of course, is very like the method of the Dogmatist]; he enters into discourse with the patient and his friends, and is at once getting information from the sick man and also instructing him as far as he is able, and he will not prescribe for him until he has first convinced him; at last, when he has brought the patient more and more under his persuasive influence and set him on the road to health, he attempts to effect a cure. Now which is the better way of proceeding in a physician and in a trainer? Is he the better who accomplishes his ends in a double way, or he who works in one way and that the ruder and inferior?"

A few practical medical or semi-hygienic suggestions are worth mentioning while we are considering Plato; thus—Much sleep is not required by nature, either for our souls or bodies, or for the actions in which they are concerned. For no one who is asleep is good for anything any more than if he were dead; but he of us who has most regard for life and reason keeps awake as long as he can, reserving only so much time for sleep as is expedient for health, and much sleep is not required if the habit of not sleeping be once formed.

In the following passage from the *Laws* of Plato we have a good unconscious description of what would apply to the empirical school of physicians; they had not come into existence in the time of Plato, but we shall have to make mention of them presently. In speaking of the inferior kind of doctor who attends slaves, Plato says:

"Of this you may be very sure that if one of these empirical physicians, who practise medicine without science, were to come upon the gentleman physician, talking to his gentle patient and using the language almost of philosophy, beginning at the beginning of the disease and discoursing about the whole nature of the body, he would burst into a hearty laugh—he would say what most of those who are called doctors have at their tongue's end: 'Foolish fellow,' he would say, 'you are not healing the sick man, but you are educating him, and he does not want to be a doctor but to get well.'"

There is a fine passage in which Plato points out the impossibility of any art imposing upon itself universal rules:

"Let us put to ourselves the case of a physician who is about to go into a far country, and is expecting to be away a long time from his patients; he leaves written instructions for the patients or pupils under the idea that they will not be remembered unless they are written down. But what would you say, if he came back sooner than he intended, and owing to an unexpected change of the winds or other celestial influences, some other remedies happened to be better for them, would he not venture to suggest these other remedies, although differing from his former prescription? Would he persist in observing the original law, neither himself giving any new commandments, nor the patient daring to do otherwise than was prescribed, under the idea that this course only was healthy and medicinal, all others noxious and heterodox? Viewed in the light of science and true art, would not all such regulations be utterly ridiculous?"

So great was the influence of Plato upon the school of the Dogmatists that Dexippus of Cos, one of the immediate followers of Hippocrates, was induced to defend the absurd notion that liquids, or at least the more subtle parts of them, passed into the lungs, because this belief had been enunciated by Plato in the *Timæus*.

We have seen that Plato had a good many things to say about medicine, but he was not specially interested in it. The extraordinary interest of the modern world in medicine and disease is wholly alien to the Platonic conception of them. To Plato, as to the ancient world generally, disease was a tiresome and meaningless exception to the ordered regularity of a harmonious life which no philosophic mind would waste time in studying. The ordinary citizen ought to be healthy, sane, and strong, and the man who was properly occupied had "no leisure to be ill." Focused upon the State as the mind of the antique world undoubtedly was, the needs of the individual were less minutely considered than is the case with us, and not only sickness but also old age was apt to come off second best. With the increase of the apparatus of living and the general complexity of modern life, every aspect of existence is subjected to an almost

morbidly minute analysis. Among the ancients life was infinitely more simple than with us, but it must be confessed that to some extent the simplicity was purchased by ignoring some awkward facts, such as diseases and the discomforts of old age. The fact is that with regard to the solution of many difficult social problems the ancients had a genius for cutting knots which the modern world prefers to untie.

### THE EMPIRICS.

It is hardly surprising that the school of Dogmatists with their philosophical disquisitions and hair-splitting dialectics should have aroused the natural antagonism of the so-called practical man, who prides himself on his contempt for all theories. Accordingly, in direct opposition to the Dogmatists arose the school of the Empirics, and certainly as against the Dogmatists these reformers had a very definite case, but unfortunately, as happens with all reactions, they became characterized by the most extreme and even absurd views. The founders of this school were Philinos of Cos and Serapion of Alexandria (fl. 280 B.C.). They were the pupils of Herophilos and Erasistratus of Alexandria, whose names are well known to all students of anatomy, and they took Aristotle for their intellectual leader. As opposed to the Dogmatists they declared the attempt to search after the ultimate causes of phenomena entirely vain: at the same time they were active in endeavouring to elicit the immediate causes.

Serapion, in addition to writing with great vehemence against Hippocrates, was almost exclusively occupied in researches on remedies and entirely neglected diet; the remedies he made use of for epilepsy have a strong savour of superstition about them, for, apart from castoreum, he advised the brain of the camel, the heart of the hare, rennet from a seal, and the blood of the tortoise.

A special stimulus was given to this school by the immense commerce of the Ptolemies, which had brought to light a large number of new medicines, with which it was possible to experiment in a purely empirical fashion. Many physicians occupied themselves entirely in experimenting with new remedies without paying any attention to the theories of the Dogmatists. They are only known to us from their preparations of certain composite remedies. In those days it was the fashion for kings and princes to take an interest in medicine, as was the case with Attalus, King of Pergamos, and Nicomedes, King of Bithynia. Attalus cultivated in his garden various poisonous plants, such as aconite, belladonna, hemlock, and henbane, and tried the effect of antidotes, several of which became known by his name. More celebrated still was Mithridates, King of Pontus, who took a poison and an antidote every day to render himself immune to poisons.

The main intellectual support of the school of Empirics, however, was derived from the influence of Pyrrho (fl. 340 B.C.), the founder of the Sceptical school of philosophy, which was contemporary with the great philosophic schools of the Stoics and Epicureans. Pyrrho came from Elis, and first followed the profession of a painter, but is said to have been attracted to philosophy by studying the writings of Democritus. He accompanied Alexander the Great to India, and, according to a tradition, came in contact while there with the Sages of the East, from whom he seems to have carried away that strange impassiveness and detachment which he strove in after life to reproduce. He lived poor but universally honoured, and died about 270 B.C., when nearly 93 years of age.<sup>5</sup>

The philosophy of Pyrrho denied everything, because according to it there are equal reasons for the affirmative and negative in all propositions. We ought not, therefore, to maintain anything, not even our own experience. To Pyrrho it seemed impossible to know the true nature of things, for our perception only shows us things as they appear, not as they really are in themselves. The only correct intellectual attitude, therefore, which a man could adopt was one of "suspended judgement." This philosophy of doubt limited all investigation to the narrow sphere of sense knowledge. There was nothing absolutely new in this; the Eclectic school of philosophy in particular had given rise to Sceptics, and Parmenides as well as other philosophers had opposed the knowledge we get from our senses to that which we obtain by the power of the mind.

Put shortly, the view of the Sceptics was this: In the case of any given phenomenon we admit it as an appearance to ourselves, we do not make positive statements about the nature of external objects in themselves. "That honey is sweet I refuse to assert; that it appears sweet I fully grant,"

says Timon, the disciple of Pyrrho. Man, as distinguished from other animals, has in the sphere of phenomena a faculty of following the process of things and retaining it. In virtue of this he remembers what phenomena he has observed accompanying each other, what preceding and what coming after, so that when the first members of the sequence are presented to him the rest are revived. Thus the Sceptic did not refrain from inferring the existence of fire when he saw smoke, or the existence of a wound when he saw a scar,<sup>6</sup> but of course he had to see the smoke and the wound. Now this scepticism differed from modern agnosticism, as, according to it, you could only infer what you did not see from what you did see, consequently the theory of the existence of atoms and pores in the body was repudiated, because atoms and pores were things which could never come within the range of sense perception. Hence such an induction as Kepler's of the movement of the planets in an ellipse would have been impossible for this school; in fact the immense part which working hypotheses have played in modern science was far from the thought of the ancient Sceptic.

The early followers of Pyrrho consisted almost entirely of physicians, who gradually formed the Empirical school of medicine. They rejected all judgements which are not immediately derived from sensations, and, like Pyrrho, they confessed that they were completely ignorant of the essence of things, affirming further that the essence was impenetrable because it escapes the recognition of the senses.

They paid particular attention to the totality of symptoms without occupying themselves with the nature of disease or its causes; for, they said, medicine is concerned with the cure of disease, not with the cause; they did not want to know how we digest but what is digestible. In subjecting the art of observation to fixed and invariable rules they rendered science a more important service than most of the speculations of the Dogmatists. No attempt, however, was made to comprehend or search into the hidden causes of symptoms, but the whole art and science of medicine became for them reduced to a system of therapeutics and of therapeutics only.

In endeavouring to find out what particular line of treatment would get rid of a particular set of symptoms they employed three methods, which became known as the "Tripod of the Empirics":

1. A man's own chance observations.
2. Learning from his contemporaries and predecessors—history.
3. In the case of new and strange diseases drawing conclusions from those most similar to them—analogy.

Later on a fourth method was added called "epilogism." This was the process of inferring preceding events from the present symptoms.

The Empiricists resembled Hippocrates in paying great attention to clinical observation, and, like him, they were guided in treatment at the bedside almost exclusively by experience. Like him, too, the Empirics attached great importance to climate, and they went so far as to assert that remedies which were necessary at Rome would have no effect in Gaul, and that a line of treatment which might be useful in that country would be quite inapplicable in Egypt. Consequently they did not in medicine admit rules which had a universal application. In one respect they may be said to have surpassed Hippocrates in that they systematized the technique of medical procedure and sought to free clinical methods of thought from the subjectiveness of the individual observer.<sup>7</sup> Unlike Hippocrates, the Empirics made no attempt to reach general laws from isolated facts, but we feel some sympathy with them when in opposition to the Dogmatists they asserted that "the husbandman and navigator are not trained by disputations but by practice." The important question is not what causes disease but what dispels it. Diseases are not cured by talk but by drugs.

Perhaps the most celebrated representative of this school was Menodotus of Nicomedia (fl. first century A.D.), who was less intransigent than most Empirics, for he did not insist upon an inherent opposition between observation and reasoning, between facts and explanation, between mind and experience. He also seems to have recognized the value and purpose of a provisional hypothesis, but he did not hesitate to write with some violence against the Dogmatists, speaking of them sometimes as "mere followers of routine," at others as furious lions. In his eyes medicine had no other aim but utility and fame and could never aspire to the title of science. The other best known name belonging to this school is that

Heraclides of Tarentum, who lived in the early part of the second century B.C. In addition to his medical studies he devoted some time to the investigation of poisons and wrote much upon antidotes, of which opium and hemlock formed the base. He was the only member of the Empirical school whom Caelius Aurelianus of the Methodist school thought worth refuting. His treatment of madness was quite rational: he first put the patient in a dark room, bled him, purged him every day, and applied fomentations to the head. He wrote a book of prescriptions for soldiers, and also upon remedies for affections of the skin and falling out of the hair, and in fact gave rise to the art of cosmetics which became widely spread in Alexandria.

As we have said, the Empirics were indebted to the Sceptics for their intellectual background. As a school of medicine their existence continued for a considerable time even in the early part of the third century A.D., in which Sextus Empiricus flourished, a younger contemporary of Galen, and one who was himself partly an Empiric and partly a Sceptic, and it is from him that most of our knowledge of this school of medicine is derived. Sextus maintained that scepticism alone can make man happy, because it teaches that nothing is naturally good or bad. Like the Sceptics generally Sextus was disposed to consider phenomena true for practical purposes; he did not deny that some useful knowledge was traditional and might be communicated by speech or writing, for no man's sole experience is sufficient to give him all useful knowledge, but he rejected all scientific investigations of phenomena as idle inquiries. He did not realize that all scientific knowledge means the recognition of the interrelations of phenomena.

From what has been said it will be easily understood that the Empirical school was more satisfactory in practice than in theory. Attention was focused upon the requirements of the sick man, without elaborating any hypothesis as to the cause of his sickness. By keeping close to the facts, eschewing theories, and by the careful observation of symptoms, not only were useful contributions made to medical knowledge, but the imagination was held under some sort of discipline, prevented from running riot and indulging in the cruder forms of superstition. Collecting facts is always useful, but it is the beginning and not the end of medicine.

We have seen how one of the most powerful influences in giving rise to this school was the sceptical philosophy of Pyrrho, which attracted so many physicians. Scepticism in homoeopathic doses may often serve as a useful antiseptic, so to speak, to a dogmatism which is growing fixed in routine, but when pushed to its logical extreme scepticism tends to believe in its own sceptical disbeliefs. In a sense it is a sign of the world weariness and disillusionment which began to overtake Greek thought in the third century B.C. All extremes tend to produce their opposites, so that a period of Agnosticism is likely to be followed by an outburst of Gnosticism. The entire mistrust of the senses, and indeed of the reason, gradually urged the spirit to search for truth beyond the limits of natural knowledge to some possibly higher source transcending time and space, and this search, aided by impulses streaming in from the East, eventually found a resting place in the philosophy of Neo-Platonism. There is little doubt that the position of scepticism is one in which the human heart can never permanently acquiesce, and if, as was said by Vauvenargues with profound insight, "Great thoughts come from the heart," the intellectual part of man's being will remain equally unsatisfied.

(To be continued.)

It would appear from W. Bredt's Report for the year 1922 that the supply of quinine is much in excess of the demand. Although the stock of quinine sulphate in London fell during 1922 the price, which was 5s. 3d. at the beginning of 1920 and 3s. 5d. at the beginning of 1921, fell in 1922 to 2s. 1½d. The export of bark from East India, Java, and Africa fell from 2,647 packages in 1921 to 340 in 1922, and the exports of quinine from Java indicate a similar decline. The international stock of quinine at the end of the year appears to have been about 23 million ounces. All these facts must militate against the efforts of the Indian Government to extend cinchona cultivation and quinine manufacture.

## MEDICAL, SURGICAL, OBSTETRICAL.

**ALBUMINURIC RETINITIS AS A PROGNOSTIC SIGN.**  
The importance of albuminuric retinitis as a grave sign in prognosis is now well established. The occurrence, therefore, of a case of recovery of the retinae from the characteristic changes due to nephritis is worthy of record. One looks on the discovery of this fundal lesion as allowing but a short lease of life—in other words, a period of from six to twelve months at the longest. The case would seem to show that if the nephritis could be recovered from the retinitis might also be capable of cure.

A youth aged 15, rather big for his age, in October, 1914, had double pneumonia, with left empyema, which was opened and drained in the London Hospital, and from which he made a good recovery. About the beginning of May, 1915, his urine became black, like porter. There was no skin rash nor sore throat, and the condition was not scarlet fever. In June he was anaemic, with oedema of face and legs, which pitted on pressure; there was no desquamation anywhere. He had slight diarrhoea. The urine (specific gravity 1030) was dark red, solid with albumin on boiling, thick curds with nitric acid. Only about half a pint of urine was passed in a day; albumin amounted to 10 grams per litre. The oedema of the legs, scrotum, and body all ceased, and I admitted him into hospital, where, with a mixture of urotropine and the aid of Southey's tubes, the oedema gradually diminished over a period of some months.

By May 15th of the next year (1916) the boy looked well, and the oedema had all gone. He said, however, that he could not see clearly, and especially could not read. The urine still amounted to 3 pints daily (specific gravity 1015, albumin 9 grams to the litre). I found that he had marked albuminuric retinitis, especially in the right eye, which was the worst from the point of view of vision. There was a large white circular patch at the macula, surrounded by a typhoid-like ring, and also slight neuritis of disc, but no ye there was slight neuritis of the disc, a group at the macula, and from the macula to the disc. Shortly after this he went home with a prognosis as regards life of from six to twelve months at most.

I was called to see him again on September 15th, 1922. He had had during the previous week some abdominal pain with diarrhoea, some blood in the motions, and bleeding from the gums; there was no oedema, and no abdominal tenderness. His face was florid, his pulse slightly irregular; there were very marked large striae on the skin of the flanks, groins, abdomen, and sides of the thorax—evidences of his previous dropsy. The urine (specific gravity 1020) was full of albumin, 6½ grams to the litre. On September 20th the boy had uraemic convulsions and nose bleeding, and was admitted into hospital. The ocular fundi were examined, and were both normal. On September 22nd he had more convulsions, became comatose, and died.

Not having seen the youth from May, 1916, to September, 1922—as he had been living elsewhere—I cannot say how he had actually been in the interval of over six years, but his parents said that he had been apparently quite well, had worked hard, never complained, nor had had to lie up. He had recently become engaged to be married. One may presume at least that, although the dropsy had disappeared, the albuminuria persisted during this period of six years. But the most interesting points are: (1) the disappearance of such a condition as typical retinitis, and (2) the return to sufficient health to be able to work hard for over six years.

## ATOPHAN POISONING.

In the *Epitome of Current Medical Literature* for January 1922 appears the abstract of an interesting paper by K. Schroeder, emphasizing the value of atophan in gouty conditions, and at the same time pointing out the liability of certain cases to develop toxic symptoms from the drug. The warning that the patient should be under close medical observation when taking atophan is most necessary, as the toxic effects do not appear generally to be well known. To the symptoms of atophan poisoning—general malaise, headache, gastro-intestinal disturbance, urticaria, albuminuria—it would seem that jaundice must be added, as its occurrence in the following case could scarcely be a coincidence.

A man aged 59, who had suffered from recurrent gouty manifestations for nearly twenty years, began to take 7½ grains of atophan (phenyl-chinolin-carboxylic acid) three times daily. At the end of twelve days he developed an urticarial rash and discontinued taking the drug. Three weeks later, the urticaria having disappeared, he thought it safe to resume, and took a further 7½-grain dose. On the following day the urticarial rash reappeared accompanied by intense pruritus; on this occasion he sought advice, and although no further atophan was taken the

urticaria proved most persistent, fresh patches occurring day by day with considerable gastric disturbance for ten days, when jaundice supervened. The jaundice was of moderate depth, but no tenderness nor enlargement of the liver was apparent. The jaundice did not clear for several weeks.

## Reports of Societies.

### THE NEW TRYPANOCIDAL REMEDIES.

A crowded meeting of the Royal Society of Tropical Medicine and Hygiene was held on January 18th, under the presidency of Sir JAMES CANTLIE, when communications were read by Dr. G. C. Low and Dr. P. MANSON-BAHR, of the Hospital for Tropical Diseases, London, on the treatment of human trypanosomiasis by the new drug known as "Bayer 205," and by Dr. C. C. CHESTERMAN of the Belgian Congo, on the action of tryparsamide in sleeping sickness. Some account of the earliest work on the former compound appeared in the BRITISH MEDICAL JOURNAL of September 23rd, 1922 (p. 569), and on the latter compound on December 16th, 1922 (p. 1183). The composition of "Bayer 205" is not known, but it is believed to be a dye containing amino naphthalene-sulphonic acid with complex formula. Tryparsamide is a pentavalent arsenic compound and a derivative of atoxyl.

#### "Bayer 205."

Dr. G. C. Low said that the first experience of his colleague and himself with regard to "Bayer 205" was in 1921, when Sir David Bruce, having received some samples of the drug from Germany, handed them over to Dr. C. M. Wenyon for certain experiments on infected mice, and some of Dr. Wenyon's supply was given to him (Dr. Low) to try on his first human case. At the same time Dr. Manson-Bahr was able to get in touch with Dr. Hennings, of Bayer and Company, the well known aniline chemists of Germany, who had continued to supply Dr. Manson-Bahr and himself with an amount of the drug adequate for the treatment of the cases of trypanosomiasis under their care. Acknowledgement was due to Dr. Hennings and the Bayer firm for their invariable courtesy. The drug had been used by Dr. Manson-Bahr and himself in nine cases, seven of which had recovered and two had died. Of the recovered cases five were present at the meeting. In eight of the cases the infecting agent was *T. gambiense*, and in one (a fatal case) it was *T. rhodesiense*. The patients were all Europeans, of a high educational standard, and able to express their feelings in a manner not easily obtainable among African natives. With their recovery there had been observed in them a return of those finer traits of character the loss of which was such a distressing feature of the disease among Europeans. In treating the cases usually 1 gram of the drug was given intravenously in a 10 per cent. solution of distilled water. He and his colleague were at first at a loss to know exactly what dose to inject, and the injections started very tentatively. Ultimately it was found most satisfactory to give a dose of 1 gram every week for ten weeks. These ten doses were regarded as the standard course, though in some cases they had been exceeded. In the majority of the cases a slight albuminuria, accompanied as a rule by the appearance of small granular epithelial casts, made its appearance on treatment, but so far as the work had gone at present "205" did not appear to lead to a chronic nephritis such as to endanger the life of the patient. In some cases an extensive erythematous rash appeared, together with pruritus, after injection. The limit of tolerance of the drug had yet to be discovered. In one case a dose of 2 grams in a single injection was well tolerated, and not followed by any grave disturbance, and in another an amount up to 6 grams in one week was injected intravenously with apparent safety.

The first of the cases he described was a man, aged 49, who showed the first signs of the illness while in Nigeria in July, 1921. He was sent home, when trypanosomes were found quite easily in the blood, and a lumbar puncture showed them to be present in the cerebro-spinal fluid as well. Some injections of "205" were given, but the drug was stopped owing to the condition of the kidneys, and antimony and atoxyl took its place. Later, from July to September, 1922, the full course of 10 grams of "205" was administered, with the result that the patient improved greatly, and he was shown to the Society a healthy man.

In three other cases the disease was contracted in Nigeria also, and the patients were sent home and put upon the course of "205," with the result that the various symptoms cleared up rapidly,

though albuminuria persisted for a long time in one case, and in another there was still a slight trace of albumin. These three men were present at the meeting.

Dr. Low also mentioned the case of a lady from the Congo who was sent home to England and admitted to hospital in December, 1921. She had been bitten by a tsetse fly, and had had fever with general malaise and body pains, and trypanosomes were found in the blood. Atoxyl treatment was started while she was in Africa, but without satisfaction, and on arriving in London she was put upon the course of "205," and left hospital in May last, apparently in perfect health, and no further signs or symptoms of trypanosomiasis had been noted.

Dr. MANSON-BAHR described one remarkable case with which he had had specially to do.

This patient, who also was present, was a man aged 37, who became ill while out in the Congo in January, 1920, when both the trypanosome and the malarial parasite were found in abundance in his blood. He left for England in March of that year, the trypanosomes meanwhile disappearing and reappearing in the blood stream in an irregular fashion. No marked diminution in their numbers followed treatment with atoxyl or galyi. When he arrived in hospital in May, 1920, his clinical condition was very poor. He suffered from drowsiness, from which it was difficult to rouse him, he was emaciated, mentally depressed, and subject to slight pyrexia. He stayed in hospital for eighteen months, and had his ups and downs on various forms of treatment, quite heroic drug therapy being practised, but he never actually made any progress until treatment with "205" was started on December 1st, 1921. From the first injection the trypanosomes disappeared from the blood stream, and had never been found since. He received ten injections, although it appeared that the first had cured him, and his condition during the whole of 1922 greatly improved, he gained weight, and now was quite well, physically and mentally.

Dr. Manson-Bahr alluded to another case—that of a lady missionary on the Congo—who had recovered, and then he turned to the more sombre side of the picture and detailed two cases which had terminated fatally.

In one of these a total dose of 18 grams of "205" was given without avail, and the end came with dramatic suddenness with a succession of fits epileptiform in character. In this case there was very strong evidence that the trypanosomes lying in the brain substance were not influenced by the intravenous injections.

The other case had a first course of 14 grams of the drug, followed by improvement and relapse, after which it was decided to push the injections, and the amount of drug was increased to 2 grams at each injection, and eight injections were given during the month of November last. Again there was improvement, but the trypanosomes reappeared, the patient lost weight, deteriorated mentally, and died on January 6th.

Therapia sterilisans magna, though desirable, was probably as unattainable in human trypanosomiasis as in syphilis. The best effect seemed to be produced by giving the first three injections at close intervals, and thereafter spacing out the remainder into gram doses once a week. The effect of the drug on the specialized renal epithelium needed to be watched. The significance of albuminuria with casts need not, however, be regarded as absolutely contraindicating the further use of the drug.

Dr. A. C. STEVENSON spoke on the pathological changes in the brain in one of the fatal cases. His conclusion was that the terminal stages of human trypanosomiasis were due to the invasion of the brain tissue by trypanosomes; that the presence of trypanosomes in the cerebro-spinal fluid was only of a diagnostic value, and had probably no influence on the course of the disease; and that the spread of the parasite to the extravascular tissues was primarily the result of migration of the trypanosomes through the vessels.

Dr. C. M. WENYON described experiments in which he had given to infected mice intravenous injections of the blood stream and cerebro-spinal fluid of patients who had received doses of "205." From his limited experiments it might be inferred that the intravenous injection of 1 gram of "205" in man caused the formation of a trypanolytic substance in the blood and cerebro-spinal fluid, and that this substance was still present a week after injection.

#### Tryparsamide.

Dr. C. C. CHESTERMAN then gave an account of some work he had carried out, mainly during 1922, at a hospital of the Baptist Missionary Society near Stanleyville in the Belgian Congo. Out of more than 300 cases diagnosed as sleeping sickness during this period 40 were selected because (1) the source of their infection was known, (2) they showed definite symptoms of nervous involvement and altered cerebro-spinal fluid, and (3) they would consent to remain in the lazaret where there was no possibility of reinfection during treatment. A course of eight weekly intravenous injections of tryparsamide was given, each injection in a solution made up with boiled rain water, of a concentration equal to 3 grams in 10 c.cm.

From the results in 24 cases which had received no previous treatment (except from the witch doctor), it was evident that if the maximum dose of tryparsamide which could be injected were given regularly and in sufficient quantity to patients who were even in the last stage of the disease there was every chance of reducing the cell content of the cerebro-spinal fluid to normal, and of removing, at any rate for the time, all symptoms with the exception of those due to the permanent damage sustained by the central nervous or other systems. In ten patients who had already received varying amounts of atoxyl or tartar emetic or other remedy without any great benefit, the clinical improvement following on the administration of tryparsamide was scarcely less striking, and good results also were obtained in six cases which had first been treated unsuccessfully by the intrathecal serum method lately described by Marshall and Vassallo in Uganda. He believed the action of tryparsamide to be superior to that of atoxyl, and that its action was gradual, so that there seemed to be a minimum total dosage, which was sufficient to render normal the cerebro-spinal fluid, of about 20 grams in an average sized and well nourished patient. Successful treatment seemed to depend on maintaining the maximum safe concentration of the drug in the system for from six weeks to two months. It seemed, therefore, impossible to escape the conclusion that the active trypanolytic constituent of tryparsamide found its way into the central nervous system. The maximum tolerated dose should not exceed 4 grams a week for a full-sized adult, and if given regularly for about eight weeks it was capable of completely removing the trypanosomes from the cell content of the cerebro-spinal fluid of even the most advanced cases. This change in the fluid was accompanied by a very marked clinical improvement, fully maintained for the period—eleven months or less—over which it had been possible to make observations.

Dr. NIRENSTEIN added some chemotherapeutical considerations, pointing out that tryparsamide differed from atoxyl, firstly in the fact that the arsenic was held in pentavalent combination instead of in the less stable trivalent form, and secondly that it contained the glycine group.

#### *Atoxyl and other Treatments.*

Dr. DERWISH gave an account of his inspection of the Yei sleeping sickness camp in Mongalla Province last summer, and stated the present condition of the patients who had been treated several years previously with antimony and salvarsan, antimony and atoxyl, and various combinations. Of twenty-seven patients treated with antimony and salvarsan (after an interval of not less than ninety-two months subsequent to all treatment), thirteen were in good condition, three in fair condition, and thirteen were dead. The results had not yet undergone the full test of time, and it was premature as yet to say whether the fall in mortality meant a long period of remission of the disease or a real recovery.

#### *Discussion.*

Professor SIMPSON said that he had no doubt that excellent results had been obtained with "205," but there was a serious drawback to the use of this drug, because quite a number of the patients had not only albuminuria but casts, which implied some kidney damage. It would be extremely unsafe, in his opinion, to use this drug on a large scale in Central Africa, though it was all very well to use it among Europeans in hospital under the care of skilled physicians. His own impression was that the problem had not been brought nearer solution than it was eighteen months ago, and the proper course would be to send out a commission of medical men and veterinarians to Africa to carry out experiments with the different drugs on a large scale over a long period. He believed that the salvarsanized serum method of Marshall and Vassallo still held the field.

Sir FREDERICK MOTT said that it seemed to him probable that when the trypanosomes were found in the cerebro-spinal fluid this was an indication that they were also in the brain substance. In that event it was very difficult, as also with the organisms of syphilis, to remove them. He was in Berlin when salvarsan was first introduced, and he recalled the enthusiasm with which it was anticipated that general paralysis would be cured, but this had not been possible. It was the same with trypanosomes: once they got into the brain the case would not be cured by any of these drugs.

Dr. ANDREW BALFOUR suggested that the problem of getting at these trypanosomes in the brain substance might be solved by combining with the trypanocidal substance some vector in

the shape of a dyestuff having a certain affinity with nerve tissue. In that way—it was only a hypothesis—it might be possible to reach trypanosomes deep in the brain.

In replying on the discussion, Dr. Low said that in Dr. Manson-Bahr's recovered case, shown that evening, in which there had been well marked signs of sleeping sickness, it seemed as though the brain must have been affected, and yet the drug in some way had penetrated. His own first case showed trypanosomes present in the cerebro-spinal fluid as well as in the blood. Dr. MANSON-BAHR combated the idea that "205" was necessarily a very toxic drug. It was an aniline product and contained no metal of any sort. From work on animals it was known to be also efficacious when given subcutaneously; probably the subcutaneous method would prove more efficacious because the drug was then stored up in the tissues. He thought that too much might be made of the occurrence of albuminuria in these cases. In some instances, even with massive doses, there was no albuminuria at all, and in others the effect on the kidneys was very transitory. It was not his view that this drug was going to be a remedy for every case; probably it was not as efficacious as tryparsamide, but it was more safe. Dr. CHESTERMAN said that, so far as conditions in Central Africa were concerned, the problem of dealing with native sickness could be met by a drug which would make it possible to sterilize the peripheral blood for a period of two or three months.

#### SPHENO-OCCIPITAL CHORDOMA.

At the meeting of the Pathological Section of the Royal Society of Medicine held on January 16th Professor M. J. STEWART and Dr. LE FLEMING BURROW (Leeds) described, and showed specimens from, a case of malignant chordoma of the base of the skull (spheno-occipital chordoma).

The patient was a man of 30, who after three years' service in France was invalided from the army for "phosgene-gas poisoning." When admitted to hospital on November 28th, 1921, he gave a three years' history of cough, headache, occasional vomiting, and unsteadiness in walking. A year before he had complained of failing vision, and was found to have optic atrophy, most marked on the left side. Recently he had complained of weakness in the legs and in the right arm.

When examined on November 30th he had blurring of speech, cyanosis, and laboured respirations, with dysarthria of paretic type. Examination of the cranial nerves revealed blindness and primary optic atrophy of the left eye, with early atrophy and diminution of the visual field on the right side. The left pupil was large and immobile. The left third, fourth, and sixth nerves were weak, but not completely paralysed, and the remaining cranial nerves appeared normal. He made considerable complaint of pain and stiffness in the neck, especially when the head was flexed on the chest, but while the cervical and upper dorsal vertebrae were held rigid there was no tenderness on percussion nor on palpation. The cerebro-spinal fluid was normal in all respects, but was under slightly increased pressure.

The patient's progress was steadily and rapidly downwards. The paresis of the legs and right arm increased, and was followed by loss of power in the left arm. The respirations were laboured throughout, and the patient finally died on December 5th, apparently of respiratory failure.

*Post-mortem* examination revealed the presence of an irregularly nodulated ovoid tumour springing from the central area of the base of the skull. It was completely covered by dura mater, and was not adherent to the brain. On its inferior aspect it had extensively infiltrated and destroyed the central portion of the base of the skull—namely, the clivus, pituitary fossa, and subjacent parts. It did not appear, however, to have invaded the nasopharynx. The tumour had led to great stretching, flattening, and distortion of the mid-brain, especially the pons and crura cerebri, the optic tracts and chiasma, and, generally, the structures forming the floor of the third ventricle. The pituitary gland had been completely displaced from its bed and was flattened out on the antero-superior aspect of the tumour.

The naked-eye and microscopic characters of the growth conformed to those of chordoma. The tumour was gelatinous, transparent, and very friable, especially in its deeper parts. Microscopically it was alveolar in structure, being broken up into masses of various sizes by narrow bands of fibrous tissue carrying the blood vessels. The alveolar masses were devoid of both vessels and stroma. They were composed of epithelial-like cells—spheroidal, ovoid, and polygonal—and everywhere mucoid degeneration was in progress. To begin with, small droplets of mucin appeared in the cytoplasm, and as the cell grew older these increased both in size and in number until the typical "physaliphorous" appearance was seen. The next stage in the evolution of the cell was that the mucin droplets were discharged, and might either flow together, forming homogeneous or granular masses of varying size throughout the growth, or might simply form a vacuolated, almost fibrillated, groundwork breaking up the tumour tissue into little groups of shrunken cells. Both the intra- and extra-cellular droplets gave the staining reactions of mucin (polychrome methylene blue, thionin blue, etc.).

The authors added that some 40 cases of chordoma of clinical interest were now on record, and were about equally divided between the two seats of election of this tumour—the spheno-occipital and sacro-coccygeal regions. The small hernial protrusions of notochordal tissue from the clivus, called by Virchow “*ecchondrosis physaliformis*,” were probably much more common than this, but could hardly be regarded as genuine neoplasms. Two examples of this condition had been met with in 150 specially investigated autopsies. Virchow wrongly regarded these nodules as cartilaginous, and his term was a misnomer; the condition would be more correctly designated “*ecchordosis physaliformis*.”

#### Classification of *B. diphtheriae*.

Dr. A. J. EAGLETON read a paper by Miss BAXTER and himself on the serological classification of *B. diphtheriae*. Beginning with a historical summary, Dr. Eagleton went on to describe the investigation, which he and Miss Baxter had carried out, of 358 strains of virulent *B. diphtheriae*. The strains had been derived from a wide “catchment” area. Three hundred and forty-two of the strains had fallen into one or other of ten clear-cut groups, and amongst the remaining 16 at least four serological varieties had been encountered. Dr. Eagleton did not maintain that strains examined by different observers in different areas would necessarily fall into the same ten types which he had found—on the contrary, he would rather expect to find a multiplicity of types in existence. Some evidence was brought forward of a structural similarity between strains belonging to the different types. It was hoped that work along these lines would prove of value to epidemiology in the future.

## CARCINOMA OF THE VAGINA AND CERVIX.

### Tumours of the Vagina.

A MEETING of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine was held on January 4th, with the President, Dr. T. WATTS EDEN, in the chair, when Mr. EARLEY HOLLAND showed a specimen of primary carcinoma of the vagina.

The patient was aged 46, had four children, and on examination a hard, circular, rough, friable growth was found on the upper third of the posterior vaginal wall; the upper edge of the growth was quite separated from the cervix. The cervix looked and felt normal, the uterus was normal in size and position, and there was no palpable evidence of other pelvic disease. Rectal examination did not reveal any infiltration of the anterior rectal wall, which could be moved freely over the posterior surface of the growth. At operation the whole of the vagina and uterus, together with the pelvic cellular tissue and iliac lymphatic glands, were removed, and the patient made a good recovery.

In such cases, owing to the close proximity of the posterior vaginal wall to the rectum, and to the very small amount of intervening cellular tissue, it seemed almost certain that permeation of the carcinoma cells into the anterior rectal wall must take place at a very early stage of the growth. The question therefore arose as to whether it was not also advisable to remove the lower part of the rectum, although the operation would then become an extremely severe one.

Mr. STEVENS showed a specimen of squamous epithelioma of the vagina.

On examination of the patient, a married woman aged 53, a large flat growth, about the size of a five-shilling piece, was found on the posterior vaginal wall; at first it was thought to be an extension from a cervical growth, but this was found at the subsequent operation not to be the case. The uterus and upper half of the vagina, with the whole growth, were removed by abdominal pan-hysterectomy, after isolation of the ureters. The patient made an uninterrupted recovery, and eight weeks after the operation received a large dose of x rays to try to prevent a recurrence. Up to the present time she had remained quite well. The growth proved histologically to be a squamous epithelioma.

Dr. HERBERT SPENCER showed a specimen of adenoma of the vaginal fornix simulating carcinoma of the cervix.

The patient, a multipara aged 44, had suffered from vaginal haemorrhage for nine months. On passing the finger into the vagina a brittle growth as big as a large duck's egg, which bled very freely, was found nearly to fill the vagina; a diagnosis of proliferating carcinoma of the cervix was made. At operation, however, the growth was found to be attached to the fornix of the vagina to the left and front of the cervix. The cervix itself was normal, except for two minute mucous polypi, which were snipped off. Radium was applied; in a fortnight the wound cicatrized. Subsequent microscopic examination showed the tumour to be benign; two and a half years after the operation the patient

remained quite well and the vagina and uterus were healthy. The occurrence of a large pedunculated, benign adenoma of the fornix simulating carcinoma was very rare, and he had not come across the record of a similar case.

Dr. RUSSELL ANDREWS said that fifteen years ago he had operated on a case of primary carcinoma of the upper part of the posterior vaginal wall, by removing the uterus and vagina by the vaginal route, and the patient had remained free from recurrence. He did not think that routine removal of the rectum was justifiable in cases of carcinoma of the vagina.

### Radium in Carcinoma of the Cervix.

Mr. A. H. RICHARDSON showed a specimen of a uterus removed for carcinoma of the cervix after radium.

Laparotomy was performed and an attempt was made to remove the uterus, but was given up on account of the fact that, on separating the bladder from the cervix, the growth was opened into. Three weeks later a quantity of friable growth was scraped out of the cervical canal and 100 mg. of radium was placed in the cavity and left in for thirty-six hours. Three months later the same amount of radium was again applied for the same time; two months later it was impossible to say, on examination, that there had ever been any growth, and it was decided to operate. The patient could not come into hospital because of domestic reasons. Six months later the operation was performed, and there was no difficulty in performing radical abdominal hysterectomy. The specimen was carefully examined by Dr. Dudgeon, who reported that microscopically he could see no growth, and that on microscopic examination of several different parts of the cervix he could find a small focus of a typical carcinoma in only one place.

The PRESIDENT and Mr. AUBREY GOODWIN showed two cases of carcinoma of the cervix treated by radium before operation.

*Case 1.*—An extensive friable growth covered the whole cervix and extended over the left and posterior vaginal walls for an area of about 2 cm.; the mobility of the uterus was impaired. The growth was scraped away with a sharp spoon, and into the large cavity thus formed 200 mg. of radium bromide was introduced and left for twenty-four hours. Nearly a month later no trace of the growth could be found on examination. Wertheim's hysterectomy was performed without difficulty. Examination of the specimen showed an extensive columnar-celled carcinoma of the upper part of the cervix, but the vaginal portion of the cervix and the vaginal cuff showed a healing, granulating surface with no malignant cells to be seen.

*Case 2.*—There was a large irregular friable growth of the cervix which practically filled the upper part of the vaginal canal, extending upon the vaginal wall for a short distance. The growth was scraped away and 160 mg. of radium bromide was introduced in three tubes and left for twenty-four hours. When the patient was examined fifteen days later no trace of growth could be found. The uterus was removed without difficulty by Wertheim's hysterectomy. Examination of the specimen showed that the cervix was hypertrophied and contained several hard whitish areas; microscopically, there was adeno-carcinoma of the cervix, including hyaline changes, with much round-celled infiltration of the growth.

The PRESIDENT thought that malignant disease would in future be treated by a combination of wide surgical removal of the growth with free use of methods of radiation.

Mr. SYDNEY FORSDIKE said that it was of small value to know the weight of radium used and the length of time for which it was employed unless the nature of the screens used was also known. It had been shown that the hard beta ray, plus the gamma ray, was approximately eight times as potent as the gamma ray alone. He believed that the best way of treating deposits in the cellular tissue and pelvic glands was with the hard x ray. Better results were claimed for the treatment of the local disease with radium alone. The question arose whether radium should not be used at an earlier stage of the disease.

Mr. GORDON LUKER said that for the past two years he had been inserting 50 mg. of radium into the cervical canal for thirty-six hours, from one to seven days before the operation. In nine cases followed up from nine months to two years there had been, so far, no local recurrence. In a few other cases another application of radium had been given three months after the operation. In doubtful cases he had seen the growth almost disappear, so that operation could easily be performed later.

Dr. DONALDSON stated that the subject of radium treatment for carcinoma of the cervix was being investigated by Dr. Canti and himself on behalf of the gynaecological department at St. Bartholomew's Hospital. So far fifty-five cases had been treated, and the majority were benefited for a time. In his opinion it was much too early to discuss the ultimate value of the treatment. The carcinoma could be destroyed

locally in the cervix, but the problem remained how to free the parametric tissues and glands. At present he was trying two methods: (1) deep radiation by the operation invented by Doel (of Ghent), (2) x-ray treatment. The most urgent need at present was a scientific basis for dosage. He was doubtful whether the biological effect was the same when the amount of radium was doubled and the duration of exposure halved. A chart of the histological findings, drawn up by Dr. Canti, suggested very strongly that the time factor and distribution of the radium were perhaps more important than the quantity of radium.

### X-RAY TREATMENT OF MALIGNANT DISEASE: CLINICAL RESULTS.

A discussion on clinical results of treatment of malignant disease by x rays took place at the Medical Society of London on January 22nd. It was preceded by an exhibition of cases.

Lord Dawson, who presided, said that the Council of the Society had chosen this subject for discussion, feeling that the progress made in radiotherapy was such that it would be useful to take stock of the position. It had been decided to narrow the discussion to true malignant disease—mainly carcinoma—and to concentrate it on the clinical results, avoiding as far as possible descriptions of technique.

Dr. ROBERT KNOX then read a paper in which, after citing cases in support of his conclusions, he said that he still felt, modern improvements in x-ray technique notwithstanding, that in all cases of malignant disease in which a complete surgical operation was possible operation should be the first procedure, but that afterwards the patient should have x-ray or radium treatment of the most thorough kind. These radiations were of great therapeutic activity, and were extremely helpful in the treatment of malignant cases, but up to the present there was no clear indication that they were in any sense a specific cure for these conditions. While the primary growth could be treated and apparently cured, recurrences were almost inevitable. These, if superficial, could be dealt with by the same agent, but the deeper metastases were beyond the reach of radiation. He mentioned a case of epithelioma of the tonsil and pharyngeal wall which showed a noteworthy result under x-ray treatment, but two years later there was a recurrence at the original site, and then the treatment by the same technique failed to produce any good effect, and was followed by much sloughing of the evidently devitalized tissues. Several cases of carcinoma of the oesophagus had done well for a time under radium or intensive x-ray treatment. He had had no good results in the limited number of gastric cases he had treated. Cases of rectal carcinoma improved as a result of deep radiation, but there were no cures, nor anything approaching cures. It was important in all cases to watch the skin carefully. In the radiologist's zeal to obtain a maximum effect the skin was often damaged. Severe burns had followed upon intensive treatment. Certain manifestations of overaction might be long delayed. In the treatment of carcinoma of the breast or chest wall the pleurae and lungs might be damaged; he had seen thickening of the pleura follow heavy x-ray treatment. On two occasions lately he had escaped disaster in the treatment of abdominal conditions by giving a short preliminary exposure to ascertain the patient's response to radiations. One patient, after a short exposure to the region of the epigastrium, suffered from troublesome vomiting, followed by a slow recovery, and in ten days' time had a sharp reaction with general malaise. Dr. Knox was now trying a method of dividing the total dose over six sittings, and found that, especially in breast cases, the result was satisfactory.

The essential feature of the new methods of intensive radiotherapy, known as Erlangen methods, Dr. Knox said, was the employment of a more penetrative ray and an increase of the initial dose. It would be some time before the results obtained by this method could be accurately appraised. The use of the more penetrating rays for a longer time did sometimes cause a rather quicker response, but the new method was attended by greater risk to the patient, and decidedly more discomfort, and in many cases, with patients already debilitated by disease, it was too dangerous to use. He emphasized the value of x rays in prophylactic treatment, where they rendered very useful aid to the surgeon. One patient whom he had seen that day had undergone the operation fifteen years previously. There had been a previous recurrence in which the masses yielded to intense x-ray

treatment, and the treatment in this second recurrence had been fair to be equally satisfactory. The recurrence was of carcinoma in the scar of the operation. In another patient, also seen that day, the operation had taken place twelve years previously. He strongly urged the general adoption of post-operative treatment by x rays or radium or both combined.

Mr. SAMUEL HANDLEY believed that in the treatment of cancer both surgery and radiotherapy were essential, and that each by itself was comparatively useless. He agreed strongly as to the value of prophylactic treatment by radiations. During the last fifteen years he had made it a rule that cases of breast carcinoma on which he had operated should have a subsequent course of treatment by x rays, and almost all the superficial recurrences just under the skin which had occurred in his experience were in the few cases which for one reason or another had escaped this prophylactic course. Surgeons ought to be very grateful to radiologists for the attempts they were making to deal with cases in which surgery was useless, though he could not help thinking that the claims made for the new methods of radiation in some quarters were excessive.

Dr. REGINALD MORTON said that it was less than the truth that 95 per cent. of the cases of malignant disease brought to the radiologist were brought to him only because they were too far advanced for any other measure. The question of the x-ray treatment of malignant disease resolved itself into one of dosage. It was well known that there were several ways of administering x rays. As between a fractional dose method and the administration of the full dose in a single sitting his preference would be for the latter. A great deal was heard about extravagant claims for intensive x-ray treatment, but it would be found that such claims were not made by the people really responsible for treatment by the Erlangen method. As to the dangers of this treatment, there should not be, with proper technique, any severe reactions on the skin. In any case, the reaction following overdose of the type of radiation now in use had little in common with the x-ray burn so rightly dreaded. In the course of his own work with intensive radiation during the last two years it had happened twice that a patient, unobserved, had made a movement during treatment, and got a double dose on a particular field. The patch was sore and unpleasant, but it healed up; it was quite a different lesion from the old-fashioned burn obtained with more or less unfiltered rays. A great deal had been heard lately about anaemia following radiations. He and a colleague had done many hundreds of blood counts on persons subjected to x-ray treatment, and it was very rare to find a case in which the red cells were reduced by more than about 5 per cent. The diminution of red cells was not found to anything like the extent sometimes suggested.

Mr. LOCKHART-MUMFERY said that his experience of the new Erlangen method amounted to only five or six cases. He had hoped a great deal from it, but he did not think it was going to be of very great assistance. X rays, like some other methods apart from operation, would occasionally cure cases of cancer. He had seen a patient cured of unquestionable cancer by arsenic, and two others cured apparently by colloidal copper. The truth was that the vitality of the cancer cell was rather below that of the normal cell; in carcinoma the margin was very narrow, in sarcoma rather wider. If, therefore, the cancer cell could be devitalized by any agent from whose poisonous action the normal cells were immune, the growth would be cured. Those who had been cured of cancer by arsenic were people who were tolerant of arsenic—a tolerance not shared by their cancer cells. X rays had the same result if a dose could be discovered which would kill the cancer cells in a given patient without harming the neighbouring cells. The whole problem was the gauging of the dose, which was extremely difficult. One of his patients, whose normal tissues were no doubt particularly susceptible to x rays, had died, following Erlangen treatment.

Dr. GILBERT SCOTT said that to tackle the problem of the treatment of cancer by radiation some technique must be devised which would not only destroy the primary tumour—on which all their efforts were apt to be concentrated—but would check the spread of the growth also. The fault of present-day methods was a too local application. His impression was that the destruction of the secondary cells required very small doses. With regard to blood changes, he believed that serious blood changes in patients receiving radiation treatment were a sign of overdose. He himself would not use the word "cure" in connexion with malignant disease; he had seen a recurrence in the sternum twenty-two

years after the removal of the breast. But the value of x-ray treatment should not be assessed merely on the ground of its capacity to kill a tumour; x rays, even when they effected nothing like a cure, often brought an immense comfort and relief to the patient.

Dr. DOUGLAS WEBSTER said that radiation might have one of three aims: (1) prophylactic, in collaboration with the surgeon; (2) palliative, in inoperable cases; (3) curative, in a very small number of cases of malignant disease, apart from superficial epitheliomata of the basal-cell type, where a good proportion of success might be looked for. An American radiologist recommended that in cases of superficial epitheliomata the patient after a clinical cure should report every six months for five years, so that any slight recurrence might be detected immediately. Spino-cellular epitheliomata were very much more resistant to radiation, yet many cases were reported cured. He gave some examples of the pitfalls and difficulties of the statistical method of approach. For example, in Frankfurt the death rate from cancer in 1918 and 1919 was given as 21 per cent., and about the same in Munich, but in Berlin, Leipzig, and Hamburg it was said to be about 60 per cent.

Mr. GORDON TAYLOR said that he believed in the prophylactic value of the post-operative treatment of cancer by x rays, and for the past twelve years all the breast cases on which he had operated had been so treated. He had gone farther and had introduced radium into the area at the time of the operation, but with unfortunate results. He placed radium (50 mg.) generally into the second and third intercostal spaces, and left it there for six or twelve hours, but about eighteen hours after the operation many of these patients suffered extreme shock, and there was no difference in his technique to account for it save the insertion of these tubes of radium.

Dr. J. E. A. LYNHAM gave some account of the results of the Erlangen method, with fractional doses, as employed at the Cancer Hospital. The results so far as they had gone had sufficed to show that the new treatment would be valuable in a certain number of cases. After the first dose he could nearly always tell, within a few days, whether or not the patient was going to do well under the treatment; patients who were going to do well looked and felt better from the start. Another point was that with the same set voltage, milliamperage, and distance there was a considerable variation in the skin reaction. The average patient got a very faint erythema, some patients got bronzing, and a fair number showed no skin reaction at all. It was not safe to base a deep-therapy dose on what appeared to him to be a widely varying factor. The impression must not be conveyed, in discussing the x-ray treatment of carcinoma, that there were good results in a large percentage of cases. But surgeons who spoke in a disparaging way about radiology lost sight of the fact that the radiologist usually had to deal with the failures and the hopeless cases. When the radiologist did see a case which was a good one for radiotherapy, but at the same time was operable, he always referred it first to the surgeon. The speaker did not believe in giving prophylactic doses until the patient had got over the shock of the operation; therefore six or eight weeks' interval usually elapsed before radiation was begun. He mentioned one case, obstinate to radiation, of which he heard that the nodules had disappeared in a remarkable manner following upon the patient's visit to Lourdes, but the disease came back again, and the patient died. The case suggested the power of mind over disease, and he thought there was a lesson in it for surgeons, who when they referred patients to the x-ray department might well do so in a tone, not of despair, as too frequently happened, but of hope and encouragement.

Dr. KNOX, in replying on the discussion, said that with the small quantity of radium used in Mr. Gordon Taylor's cases, and with the short exposure, he had never seen anything like the reaction of which Mr. Taylor had spoken. He deprecated, with some other speakers, the extravagant claims made for the Erlangen method. These claims were not made by those who were actually practising that method. He thought that x-ray technique was capable of much greater improvement, perhaps even of revolution. He had sometimes imagined that its future would involve the use of a whole battery of x-ray tubes, so that the patient would be, so to speak, exposed to an x-ray bath. Some such means of procuring a widespread action on the tissues was well worth investigating.

## PAROXYSMAL TACHYCARDIA.

At a meeting of the Medical Section of the Royal Academy of Medicine in Ireland on January 5th, with the President, Dr. T. GILLMAN MOORHEAD, in the chair, Dr. LEONARD ABRAHAMSON read a paper on two cases of paroxysmal tachycardia (with electrocardiograms). He remarked that the term "paroxysmal tachycardia" had been applied to various conditions differing essentially in mechanism. In dealing with a sudden acceleration of the heart rate, it was imperative to avoid confusion, to specify where possible the exact mechanism. Thus a case might belong to one of four groups: (1) paroxysms of simple or sinus tachycardia; (2) paroxysms of auricular fibrillation; (3) paroxysms of auricular flutter; (4) paroxysms of extra-systoles. Where the mechanism of a paroxysm was obscure the diagnosis had not been made, although one might be able to decide from certain clinical criteria, such as sudden onset of attack, unchangeable rate, and sudden termination, whether one was dealing with a paroxysm of abnormal tachycardia or with a paroxysm of normal tachycardia. The first case exemplified a paroxysm of extra-systoles.

The patient, a female aged 22, who presented a stenosis and regurgitation of the mitral valve, when first seen was suffering from a paroxysm of tachycardia, which had commenced abruptly on the previous day. Electrocardiograms showed a series of extra-systoles, rate 200 to 205 to the minute. Whilst the tracings were being taken the attack stopped abruptly with a long pause, but recurred in a few moments. The interparoxysmal period showed a large number of extra-systoles arising from different foci, some in the auriculo-ventricular node, with others in the auricle above the node; the paroxysm itself was believed to spring from a low level in the node.

The second case demonstrated a paroxysm of auricular fibrillation, rate 170 to 180, occurring in a male aged 58, the subject of advanced myocardial disease. The tracings were shown in order to demonstrate the difference in the mechanism of that paroxysm and of the preceding one. After the subsidence of the attack the patient developed a chronic auricular fibrillation.

The PRESIDENT said that he had recently seen a case in which the patient was immediately able to check the tachycardia by pressing deeply on each side of his neck.

### Milk Anaphylaxis.

The PRESIDENT read a note on milk anaphylaxis, using the latter term as signifying a special sensitiveness on the part of some patients to milk. He registered a protest against the almost universal and indiscriminate use of milk in cases of gastric disorder, and pointed out that in many cases the use of that fluid merely aggravated the condition which it was intended to cure. Cases illustrating his contention were reported, including one case in which, after two operations had been performed and nothing wrong had been found in the abdomen, relief was immediately obtained by stopping all milk food. On one or two occasions milk was given accidentally during the progress of the case, each time followed by the occurrence of acute gastric pain and vomiting.

Sir JOHN MOORE said that in cases of enteric fever he had often seen milk acting as a poison, and in such cases he had substituted whey and egg water; raw meat juice and port wine were also good substitutes.

Dr. L. ABRAHAMSON had known of a case of mucous colitis, which had been treated medically, x-rayed, and operated upon and was no better, having been on a milk diet for about two years. The patient was then put on meat juice, after which he made a complete recovery, while appendicectomy and other measures had done him no good at all. Dr. PERCY KIRKPATRICK said that Dr. Tweedy had regarded milk as the worst form of food which could be given to a patient suffering from eclampsia, as he regarded eclampsia as a form of anaphylaxis due to milk poisoning. Dr. T. J. D. LANE was of opinion that the great point in those cases was to find out, when milk disagreed, if it was due to anaphylaxis or not. If the patient gave an anaphylactic response to ordinary milk, and not to boiled milk, he thought that was a point in favour of anaphylaxis.

Dr. G. E. NESBITT, Dr. H. F. MOORE, Dr. KENNEDY CAHILL, Dr. R. J. ROWLETTE, and Dr. C. PILE also took part in the discussion.

### Renal Efficiency Tests.

Dr. G. E. NESBITT read a note on renal efficiency tests, and demonstrated three which he had found most serviceable—namely, the urea concentration test, the estimation of blood urea, and the excretion of phenolsulphonephthalein. He had followed, for the most part, the methods and technique recommended by Professor H. Maclean, and he could testify to their

excellence. It was only fair to say that any of Maclean's methods he had tried had been equally satisfactory. Acting on suggestions of Professor Caldwell he had made some minor alterations in the estimation of blood urea which he thought were decidedly advantageous; one was the addition of a side tube by means of which alcohol could be added at any time to control frothing, and another was the immersion of the blood tube in a jacket of warm water during distillation, which brought over the ammonia much more thoroughly and quickly. As regards the value of the tests, he thought that no just opinion could be expressed in a doubtful case of nephritis based on ordinary findings alone, nor should serious genito-urinary surgery be undertaken until the condition of the kidneys had been ascertained by some such means as these tests. Not the least value of the tests was the possibility of demonstrating sound renal function in cases which had been rejected for life insurance, or had been treated as chronic invalids on account of the presence of albumin and even casts in the urine.

Dr. H. F. Moore said that the tests should be carried out in conjunction with the ordinary physical examination of patients. Care should be taken to use an efficient colorimeter for the phenolsulphonephthalein test.

Dr. V. M. Sykes had found the curve of water excretion a very simple and reliable guide in these cases. Mr. C. E. Brewster had carried out a critical examination of the blood urea estimation in conjunction with Dr. Fearon with a view to the discovery of fallacies, and they had found several; Dr. Nesbitt, working independently, had come to the same conclusions. He thought the use of the warm water jacket was new and an important addition to the technique.

### "LUNG SPLINTING" FOR PULMONARY TUBERCULOSIS.

A MEETING of the Ulster Medical Society was held in the Medical Institute, Belfast, on January 4th, with the President, Professor R. J. JONESTONE, F.R.C.S., M.P., in the chair. Dr. S. H. STEWART read a paper entitled "Some preliminary observations on lung splinting in the treatment of pulmonary tuberculosis." He said that rest was a fundamental factor in the treatment of all forms of tubercle, and pointed out many facts drawn from different sources in support of that aphorism. The operation for letting in a gas to the pleural cavity and thus giving the lung complete rest was not always feasible. Dr. Stewart then demonstrated practically, on an assistant, his method of "lung splinting," and showed the mechanical reasons for the various adjustments. He gave notes of some cases which he had treated by the apparatus, with statistics taken before and afterwards. All the patients wore the apparatus without inconvenience, and were benefited.

The President asked whether pulmonary tuberculosis was always primary and whether x-ray examination had been made to ascertain the amount of diminution of movement.

Dis. HALL, RANKIN, CALWELL, TRIMBLE, McKISACK, BURNS, and FOSTER COATES joined in the discussion. The chief points raised included the question of tissue susceptibility, and whether movement acted simply as a mechanical distributor. It was pointed out that the meninges were the least mobile part of the body and yet tuberculous infection was always fatal, and that high altitudes involved increased lung action and yet brought cure. The suitability of the apparatus for girls of rather frail physique was questioned. Congratulations were offered to Dr. Stewart for the ingenious manner in which he had met the various difficulties and mechanical complications.

Dr. W. L. STONEY read a witty paper on "Some realms of gold untravelled yet by vaccine therapists," which was much enjoyed by the members, and the Chairman expressed the thanks of the meeting.

A MEETING of the London Association of the Medical Women's Federation was held on January 15th, with the President, Dr. LOUISA MARTINDALE, in the chair. Dr. ESTELLE COLE, in a paper on the psychology of Freud and its application, defined certain basic ideas of the Freudian psychology and the use of the terms "conscious," "pre-conscious," and "unconscious." She described the biologic non-moral aims of the individual as expressions of the unconscious. These aims, being in conflict with the morality of civilized society, were repressed, the continual warfare giving rise to "conflict." Dr. Cole emphasized the Freudian doctrine of psychic determinism, or the causal determina-

tion of ideas and symptoms, and discussed the wide interpretation of the term "sexual" introduced by Freud. She described the dream as the preserver of sleep, and argued that the pictorial representation, or symbolism, of the dream was not the confused jumble that it appeared on superficial examination. The Freudian method of analysis was then described, and a list of abnormal conditions benefited by analysis was given.

## Rebickus.

### SCIENCE AND HUMAN AFFAIRS.

There can be no more enthralling subject for study than the persistent progress of human thought through the ages. "Persistent" is the right word; it might even be amplified to "irresistible," for the more deeply the matter is pursued the more apparent does it become that the golden thread of progressive thought has never been broken, and that it traversed even the Dark Ages. This point is well brought out by Dr. WINTERTON C. CURTIS in his book *Science and Human Affairs*, the earlier chapters of which are devoted to the demonstration of this fact of continuity. The author is primarily concerned with the birth and growth of scientific thought and knowledge, and traces this development with a wealth of interesting and deftly used detail. He shows the gradual ascent of natural knowledge—that is, knowledge gained by observation of natural phenomena, fearless knowledge, neither mystery-ridden nor with knees bent in deference to false authority, but moving steadily forward with open eyes and open mind. So free a spirit must inevitably meet with obstruction, but, if it is truly scientific, it knows not despair nor dismay. From all its trials it has emerged with increased strength until to-day it finds some place in almost every system of Western thought, and is a part of every rational thinker's mental equipment.

The foundations of practical science seem to have been laid not later than 4500 B.C. in earliest civilized Egypt, culminating in the great Pyramid Age (3000-2500 B.C.). But the Egyptian, despite the wonder of his achievements, was limited in his thinking and had little power to generalize. It was left to the Greek to abstract and generalize, and to grasp the principles underlying the product of human eyes and hands; it was he who sowed the seed of modern scientific thought. The Roman period was more notable for practical accomplishment than advance in thought; and with the advent of the early centuries of the Christian era certain fundamental social changes, and antagonism to pagan culture, were responsible for the decline of science, which by this time had lost its initial impetus. But it survived the self-delusion and obtuse authority of the Middle Ages, and by 1450 had recovered its independence. Men awoke to the truths of natural science, and rapid advance became possible. In the succeeding centuries numerous societies and academies arose (the Royal Society of London was incorporated in 1662) which were not part of the formal educational system of the period. The isolation of scientific workers was thus ended and their solidarity established. Henceforward the march of science was steady and sure.

Dr. Curtis is a biologist, and his historical review of science in general, in Part I of the book, leads to an exposition of modern biological science in Part II. The cell doctrine, the theory of organic evolution, and the growth of zoology are discussed with the authority of an expert. The author lays stress on the many points of contact between biology and medical science. "The more scientific medicine becomes," he writes, "the greater will be its demands upon zoological science." This section of the book is rich in detail and does not admit of summary; it must suffice to say that it is the keystone of the work as a whole.

Part III is on the present importance of science, and it is here most particularly (though Dr. Curtis never loses sight of his main thesis) that the book lives up to its title. This part may be summed up as a plea for, and a justification of, the scientific spirit and point of view in all branches of human activity. The case is stated with manifest sincerity and conviction. The author has unbounded faith in the capacity of the scientific mind to secure ever-increasing benefits for mankind, to clear away the fog of speculative thought, to bring mystery into the open light of day, and to throw a beam into all dark places. He asks for more science in philosophy,

*Science and Human Affairs from the Viewpoint of Biology.* By W. C. CURTIS, Ph.D. London: G. Bell and Sons, Ltd. 1922. (Demy 8vo, pp. vi + 350; 30 figures. 15s. net.)

in law, in art, in sociology, and in education, believing that nothing but good can result. These chapters are provocative of thought, and are written with skill and breadth. They will no doubt excite opposition in the minds of many readers who have not had a rigorous scientific training. Dr. Curtis's plea for the open mind should disarm them. Wherever science is, he contends, there also is progress.

"The scientist believes that his rationalistic method offers a means of moving forward which sets no limit and sees no end. . . . New and more difficult problems arise from each problem solved. . . . Things undreamed of in our philosophy continually appear."

A remarkable and notable book, the product of prolonged thought and painstaking care in the selection and marshalling of material. It is worthy of a permanent place in the library of every thinker.

#### PSYCHOLOGY AND THE PARENT.

DR. H. CRICHTON MILLER has written a volume on *The New Psychology and the Parent*,<sup>2</sup> based on a course of lectures given in connexion with the Tavistock Clinic. He expresses his views clearly, and there is nothing in his book that the educated layman should fail to understand. He discusses the outstanding particulars in which parents are apt to fail in bringing up their children; explains his conception of the unconscious and the meaning of dream symbolism; and gives an account of his views as to the origin and function of the "herd" instinct. The concluding chapters dealing with the religious education and sex instruction of children will perhaps be of special interest to parents, because these questions are often felt by them to constitute a serious problem.

Dr. Miller's views approximate to those of the Zürich school, and his teaching is based largely on the assumption that the human being is endowed with ethical and religious instincts. Many psychologists would regard this assumption as more than doubtful, and the tendency in the volume to evaluate the various impulses of the human being gives rise to the impression that the New Psychology, as here outlined, has overstepped the legitimate boundaries of psychology and strayed into the regions of ethics and mysticism. Apart from any

seem to be a certain danger of ing the place of a spiritual director. He will tend to regard some forms of behaviour as "better" than others and judge his patients according to whether they are doing good to others or not. We would suggest that Dr. Miller exhibits this tendency when he expresses the view that the young man who becomes a scoutmaster is embracing magnificent opportunities for sublimating his social or parental instincts, whereas the young man who devotes all his spare time to golf is merely working off a certain amount of physical energy. We think it is justifiable to make the criticism that Dr. Miller is here assuming the parental attitude to the young man that he very properly warns parents against. Is he not tending to stand between the young man and self-realization—to obstruct his psychological freedom?

Though there is much in this book that is somewhat speculative from the standpoint of psychology it contains some excellent advice, and it may be safely recommended to parents and teachers.

#### TREATMENT BY SUGGESTION.

IN his modest volume on "*Suggestion*" and *Common Sense*<sup>3</sup> Dr. R. ALLAN BENNETT develops the view that no ailment, organic or functional, is beyond the reach of help by suggestion, provided that the patient is capable of exercising the requisite intelligence. The author is thus a firm believer in the value of suggestion, though he does not claim personally to have observed any more than its elementary applications. Theoretically, however, he would place no limitations on its possibilities as a therapeutic agent, and he can see no logical objection that can be brought against the assumption that laws exist permitting the readjustment of any relations disturbed by disease. In a thoroughly practical chapter Dr. Bennett states how he carries out the treatment of his cases by suggestion.

The author does not accept a mechanistic interpretation of life, and in the opening chapter he expounds his conception of the living organism as a self-directing unit, endowed with

<sup>2</sup> *The New Psychology and the Parent*. By H. Crichton Miller, M.A., M.D. (Edin. and Pavla). London: Jarrolds, Ltd. 1922. (Cr. 8vo, pp. 255. 5s. net.)

<sup>3</sup> *Suggestion* and *Common Sense*. By R. Allan Bennett, M.D. (Lond., M.R.C.P.). Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd. 1922. (Cr. 8vo, pp. 105. 6s. net.)

not only the power but with the will to develop. In the preface he explains that, acting on the advice of the late Dr. Charles Mercier, he decided to drop psychology and apply the principles of common sense to medicine. We do not think psychology is quite so remote from common sense as the author would seem to imply. Indeed, the sound and clearly expressed views as to the source of consciousness, and the function of the individual cell and its relations to the organism as a whole, contained in this volume embody in somewhat different language the most recent psychological teachings.

It may be that some readers of this volume will be unable to accept the beliefs of the writer in their entirety, but it is a book which can be safely recommended to the medical practitioner. It is clearly written, breathes a spirit of optimism, is free from technical phrases, and holds the attention of the reader.

#### HEREDITY IN MAN.

WE have received a copy of the first volume of a book on heredity in man by three German authors<sup>4</sup>; the intention seems to be that when complete it shall be a comprehensive treatise on general biology in its applications to medicine.

The subject of variation is dealt with in the first section by Professor Dr. ERWIN BAUR of Freiburg, who groups the principal causes of variation under three headings: (1) Para-variation, or variation by modification in idioplasmatic individuals who have grown up under similar external conditions; (2) mixovariation, resulting from the union of individuals who are not idioplasmatic; and (3) idiovariation, which is practically the same as what is generally known as mutation. The instances given in exemplification of the different types are mostly known to biologists. Professor EGGEN FISCHER discusses variations of the human body in different races of mankind from the anatomical and anthropological standpoints. Dr. FRITZ LENZ contributes two sections, which occupy rather more than half the volume. Dr. Lenz defines "illness" as the condition of one who lives on the limit of the possibilities of adaptability, and "perfect health" as the state of complete adaptability. The causes of illness are to be found neither exclusively in environment nor in heredity, though one or other of these usually predominates. The latter is considerably more evident in diseases of the mind than in other disorders; syphilis and alcohol occupy secondary, but nevertheless very important, positions. Dr. Lenz tentatively distinguishes as a true "mental" disease one of sufficient intensity to prevent a person from following his vocation, lesser degrees being regarded as "psychopathic." This is admittedly but a rough and ready division, but no idiosyncratic division is as yet possible. He agrees with Goddard that heredity is responsible for two-thirds of the cases of insanity, since in America alcoholism can be ruled out. Such a conclusion appears to be somewhat premature. Syphilis is stated to be less prevalent in America than in Europe.

Many mental diseases are dealt with, some at considerable length, from the standpoint of hereditary causation. The amaurotic idiocy which occurs sporadically amongst the Jews is considered to be homozygotic and recessive and therefore not a racial tendency. Schizophrenia or dementia praecox is regarded as the most important mental disease next to paralysis of syphilitic origin, and heredity is its only known cause. Rudin's analysis of cases is quoted, but the evidence as to whether this disease is of a recessive character or not is by no means conclusive. In discussing epilepsy reference is made to Steiner's statistics, which are held to show that there is a connexion between this disease and left-handedness.

Hysteria is defined by Dr. Lenz as a more or less unconscious and involuntary imitation of forms of illness; the patient need not necessarily have seen the form of illness which is imitated, but gives to it the form he imagines it would take. Hysteria is regarded as a form of mimicry, and analogies are drawn with types of mimicry among animals, such as insects feigning death, the hen partridge pretending she cannot fly in order to attract attention away from her young, etc. Such analogies appear to be rather forced, as the instances of mimicry given are clearly protective and the results of accumulative experience. It is difficult to believe this to hold good in hysteria; more particularly as the author limits the term to the involuntary imitation of forms of

<sup>4</sup> *Menschliche Erblchtheitslehre*. Band I. By Professor Dr. Erwin Baur, Professor Dr. Eugen Fischer, and Privatdozent Dr. Fritz Lenz. München: Lehmann. (Med. 8vo, pp. 305; 65 figures.)

disease; he proposes the word "orgoristia" for determined imitation and suggests that paranoiac-mental derangements are closely related.

The section of the book which deals with the relation of mental endowments and psychopathy is of considerable interest, though some of the generalizations verge on the humorous or the alarming. The mental condition of such men as Rousseau, Wagner, Nietzsche, Darwin, Mohammed, Napoleon, and others remarkable for great mental endowments, is discussed. Great poets, artists, philosophers, and politicians, in fact all with high mental abilities, with the exception apparently of research workers and discoverers, are, according to Dr. Lenz, the victims of orgoristia. Goethe's family is given as an example of the tendency to mental derangement in the other members of the family of talented persons. It is, as the author admits, a painful thought that the deeds and mental output of those whom we have been accustomed to regard as mental heroes should have sprung from a tainted stock. Perhaps Dr. Lenz is mistaken. As far as it is possible to understand the conclusions arrived at, they appear to be as follows: that, so long as the idea of disease is connected with the preservation of the individual we cannot acknowledge a connexion between genius and disease; but, if such idea be connected with the preservation of the race, the question at once assumes another aspect. The creative activity of the genius may help the life of the race, and, though it may injure individual preservation, be thus beneficial. A population of geniuses would be incapable of continuing to exist; but the sporadic occurrence of genius is of vital importance to the race in order that new avenues of life may be opened up. These later sections of the book make difficult but interesting reading, and may be taken to justify a hope that much may yet be done along this line of inquiry. The general impression left on the mind of the reader, unless he happens to be a supraltruist, will be that one would much prefer to leave the possession of genius to the other fellow.

#### A FRENCH TEXTBOOK OF NEUROLOGY.

A SERIES of manuals is appearing in Paris, under the general editorship of MM. Gilbert and Fournier, intended to form a library for the degree of Doctor in Medicine. We have before us the two volumes of this series devoted to the diseases of the nervous system.<sup>5</sup> The author, Dr. HENRI CLAUDE, is to be congratulated on the successful issue of his task. Into these two volumes, containing together some fourteen hundred pages, he has managed to compress a very full and fair account of the present state of knowledge. Diseases of the brain and of the spinal cord, the subject of the first volume, and in the second of the spinal cord, the system diseases, the diseases of the peripheral nerves and muscles, disorders of the sympathetic nervous system, and the various neuroses are considered.

The volumes as a whole may be recommended as a valuable and up-to-date textbook. The production of a single pen, it has gained by the absence of overlapping and inequality in treatment of different subjects, which is a common fault in some textbooks.

Probably the most valuable feature of the book, at least to the neurological student, are those sections which deal with general symptomatology and with the various syndromes or clinical pictures whose characters and interpretation are well described. There is, for example, an excellent account of aphasia and apraxia; a concise description of Wilson's disease and of other diseases of the corpus striatum is included. Though detailed criticism is impossible we may mention that the account of epidemic or lethargic encephalitis appears to us unsatisfactory and inadequate, especially in view of the increasing frequency and importance of its various sequelae.

The value of the volumes would have been enhanced had more space been given to anatomical and physiological descriptions, and particularly by the provision of more and better anatomical plates; the other illustrations are better and in many respects very valuable.

In conclusion, and from the point of view of the English reader, a tribute of praise and thanks is due to the author for a style and a diction which are both lucid and pleasant, and should go far to obtain for these volumes a wide circulation in this country.

<sup>5</sup> *Précis de Pathologie Interne. Maladies du Système Nerveux.* Vols. I and II. By Dr. Henri Claude. Bibliothèque du Doctorat en Médecine. Published under the direction of A. Gilbert and L. Fournier. Paris: J.-B. Baillière et Fils. 1922. (Post 8vo. Vol. I, pp. xi + 549; 79 figures; fr. 20. Vol. II, pp. xi + 880; 170 figures; fr. 30.)

#### THERAPEUTIC NOVELTIES.

THE thirty-fifth annual report of Messrs. Merck<sup>6</sup> of Darmstadt upon the pharmacological action of new drugs has been issued. These reports were printed in English as well as in German before the war; at present they appear only in German, but it is stated that next year an English edition will be produced.

The present volume mentions about 700 drugs, and gives about three thousand references, the great majority of the latter referring to work published in the year 1921. The references are obtained from about 400 journals published in about twenty-five different countries. These figures indicate the scope of the work and its value to anyone who wishes to find out quickly what has been written about some new drug.

The report commences with a special article of eighty-one pages on the chemistry of glucosides, dealing with the glucosides used in medicine other than the glucosides of the digitalis group. The rest of the work consists of short summaries of the literature which appeared in 1921 concerning the drugs dealt with; the summaries are uncritical, and hence the general impression given is that there exist a surprisingly large number of universal cures. This, however, is due to the poor quality of the literature dealt with, and is not the fault of the compiler.

The following are a few points worthy of mention: Two and a half pages are devoted to the new trypanocidal agent "Bayer 205," and fifteen references are given. No reference is made, however, to the new American arsenical trypanocide named tryparsamide. This suggests that the volume is more reliable for German than for non-German drugs. The subject of protein therapy occupies twelve pages, and seventy references are given; needless to say, the clinical effects reported are startling, and that cures of the majority of diseases are reported. The present state of this treatment is indicated, however, by the fact that there is no agreement as to whether the doses administered should or should not be sufficient to induce fever.

Some interesting references are given to the action of quinine upon the uterus. The conclusion arrived at is that quinine does not excite the normal pregnant uterus, and therefore will not act as an abortifacient in a healthy woman, but that it will excite the uterus in pathological conditions, and also will strengthen the uterine contractions in labour. The use of iodine as a general internal antiseptic is being revived, and it is even recommended as a specific in tuberculosis. Pregl's solution, which contains 0.04 per cent. iodine together with iodides and hypoiodites in watery solution, is recommended as a general disinfectant for local use and also as a general antiseptic for intravenous injection. Beneficial results are reported in encephalitis lethargica, disseminated sclerosis, tabes, epilepsy, arterio-sclerosis, puerperal fever, and other diseases. As already mentioned, the report gives non-critical summaries.

These are only a few haphazard examples of the subjects dealt with in the report, but they suffice to indicate the very large amount of information that has been collected; of the value of the information the reader must judge for himself.

#### THORPE'S DICTIONARY OF APPLIED CHEMISTRY.

THORPE'S *Dictionary of Applied Chemistry*<sup>7</sup> possesses all the merits befitting an encyclopaedia of chemistry. The new edition has reached the third volume; the subjects dealt with extend from Explosives to Kyrofin, which we are informed is the trade name for a substituted anilide used as an antipyretic; this is an example of the book's comprehensiveness, for the substance can have no interest beyond the historical fact that it appeared at some time among the synthetic products offered for therapeutic use. The appearance of a monograph on krypton demonstrates the same quality. The objection might be raised that a dictionary of applied chemistry should not include accounts of substances such as krypton, which have only an academic interest, but the fact that any observations on general chemistry may some day form a part of applied chemistry affords good reason for their inclusion. At the other extreme,

<sup>6</sup> *E. Merck's Jahresbericht über Neuerungen auf den Gebieten der Pharm.* 1921. XXXV Jahrgang. Darmstadt: E. Merck. 8vo, pp. 492.  
<sup>7</sup> *Thorpe's Dictionary of Applied Chemistry.* Vol. iii. By Sir E. Thorpe, C.B., LL.D., F.R.S., assisted by eminent contributors. Revised and enlarged edition. London and New York: Longmans, Green, and Co. 1922. (Med. 8vo, pp. viii + 735; illustrated. Vol. iii, £3 3s. net.)

monographs on materials like flax and hemp are not out of place, though they afford little opportunity for chemical discussion; their industrial importance justifies the description of their botanical origin, of the microscopic and physical characters of the fibres, and of the mode of preparation and uses of the products. It is pointed out that though water in which hemp has been steeped produces no evil effects on the health of the district, it destroys fish together with certain vegetable growths when allowed to flow into running water. In an interesting article of 300 words on flagstone we read the curious statement that one of the great factories of meat extract on the River Plate is flooded throughout with flags exported from Caithness. The discursiveness of the articles is further exemplified on page 461, where under iodine we find a list of some fourteen marine products, showing their content of iodine; among them are oysters with 0.00004 per cent. and mussels with 0.03 per cent.

Encyclopaedias are sometimes said to make pleasant fire-side reading on account of the wealth and variety of information given, but to be of no use for the thing wanted when occasion demands. The statement contains a certain measure of truth, but it admits equally of the construction that great services give rise to greater expectations. It is manifest, however, that the value of such a work would be greatly increased by the compilation of a supplementary volume containing a full index to incidental references, since a great number of these occur under headings not likely to lead to their immediate discovery. The subjects of greater importance receive appropriately extensive treatment, purely scientific matters being no less generously dealt with than those which have attained great industrial importance. There is a discourse on flame deserving to rank as a classical treatise written by one who is not only a successful research worker on the subject but also gifted as a writer. The article should be read by every student of chemistry. The same may be said of the article on hydrolysis. Many of the monographs contain sufficient matter to make separate volumes, notably those on explosives, fertilizers, fuel, gas, and glass. Coal gas is reviewed from many standpoints; of technological interest are the reviews of air gas, oil gas, and water gas; the substances used in gas warfare are noticed. The characteristics and the structural constitution of dyestuffs are reviewed as completely as it is possible to expect in a general dictionary of chemistry. The bibliographical references are sufficient to satisfy those who need further information than the text provides. The volume maintains the standard set in former editions and attains the full measure of improvement expected from revision.

### THE GOLD-HEADED CANE.

Dr. GEORGE C. PEACHEY's new edition of *The Gold-Headed Cane*<sup>8</sup> is an attractive work both in its form and in the matter provided by his introduction, annotations, and six fine photographic portraits of Radcliffe, Mead, Askew, William and David Pitcairn, and Matthew Baillie. This medical classic was first published anonymously, though now known to have been written by Dr. William Macmichael, Registrar of the Royal College of Physicians of London, in 1827, and passed into a second and much enlarged edition in the following year; it gave a pleasant gossipy account of the medical world in the times of the physicians mentioned above, and purported to be the memoirs of a gold-headed cane which was successively carried by those medical worthies. The third edition, in 1884, which brought the subject-matter down to the year 1858, was edited by Dr. William Munk, Harveian Librarian of the College, and added notes. In 1915 a fourth edition, with an introduction by the late Sir William Osler and a preface by Dr. F. R. Packard of Philadelphia, the editor of *The Annals of Medical History*, was brought out by the publishing firm of P. B. Hoeber of New York, and in 1920 a stereotyped issue of this appeared in this country from the Oxford University Press; this tastefully got up volume reproduced the text and illustrations of the second (1828) edition, and, like the previous editions, was an octavo.

Dr. Peachey's edition also follows the text and contains the illustrations of the second edition, but it is in quarto; his

notes are distinguished from those of the original by being in italics. His pleasantly written introduction etches in with a light hand the characteristics of the carriers of the gold-headed cane, and incidentally reveals the editor's knowledge and love of heraldry and bookplates. Among other happy touches he quotes the contemporary epigram on Francis Bacon's philosophy that "his works were like the peace of God which passeth all understanding." The additional notes show that Dr. Peachey obeys the injunction—more admitted than practised, it must be feared, by many of us—of verifying references, and by this process he throws polite doubt on some of the statements made current in this favourite classic. Further point and piquancy are thus added to the excellences of this edition, on which the editor must be heartily congratulated.

### NOTES ON BOOKS.

THE fifth edition of HEWLETT's *Pathology*<sup>9</sup> is characterized by the inclusion of certain sections—notably those on deficiency diseases, allergy, and blood-grouping—which did not appear in the last edition published five years ago. Short paragraphs have been added on encephalitis lethargica and herpes, containing a reference to the recent French work on the filtrable viruses encountered in these diseases, while a few lines on botulism have somewhat questionably been placed in relation to them. A helpful and illuminating page has been devoted to the reaction of the blood, with a table defining the exact meaning of such conditions as acidæmia, alkalaemia, alkalosis, and ketosis. The chapter on the ductless glands has been revised, and now furnishes a succinct and not too detailed account of the complicated series of changes dependent on alterations in the normal structure and function of these organs. It is perhaps unfortunate that the pancreas has not been included. There seems no reasonable doubt that diabetes mellitus is related to the internal secretion of this gland, and indeed it would have been well to have dealt with the whole subject of glycosuria in this chapter. Ehrlich's theory of immunity is still maintained in all its pristine magnificence; we imagine that its value for teaching purposes has been permitted to outweigh its inherent defects and misleading suggestions. The book is clear, concise, and comprehensive, and we wish it all the success that it deserves.

Marshal Catinot, in times so long ago as those of Louis XIV, asserted that "no man is a hero to his valet de chambre." But in these days when the valet is of little account, and the private secretary has assumed his more important and higher attributes, we find that a man may be a hero to his secretary. Mr. NEVILLE LANGTON has written a little book entitled *The Prince of Beggars*,<sup>10</sup> being some account of the beggings of Sydney Holland, Viscount Knutsford, during twenty-five years as chairman of the London Hospital. Lord Knutsford's interest in medical affairs may perhaps be traced to the fact that he is a grandson of a sometime distinguished member of our profession; he has himself played no small part in the affairs of so widely known a medical cosmos as the London Hospital. The beggar is honoured in the East and finds a place in the sun from which no one will dare to shift him; in our matter-of-fact West the beggar was a vagabond to be whipped at the cart tail, according to the direction of Tudor statutes still unrepealed. But there are beggars and beggars, and Lord Knutsford is one of the exceptional beggars whom we would not scourge but encourage. Mr. Langton's book is lightly written, and has many pretty stories within it incidental to begging. One of the best is that of an old lady who received an appeal for help for the hospital, in reply to which she wrote whole pages of religious advice, and woman-wise ended with a postscript, which ran: "P.S.—Prey without ceasing."

Dr. JOSEPH B. DE LEE of Chicago has issued the sixth edition of his *Obstetrics for Nurses*,<sup>11</sup> which first appeared in 1904. In process of time the book has undergone many changes, but the author states that it has not been necessary to make many alterations in preparing his new edition. The book is addressed to nurses, and appears well designed to meet their needs.

SMALL-POX AND VACCINATION IN THE  
PHILIPPINES.

BY

JOHN C. McVAIL, M.D., LL.D., F.R.F.P.S.G.

I HAVE been asked by the Editor of the BRITISH MEDICAL JOURNAL to write about small-pox and vaccination in the Philippines, and, in order that I may be in a position to do so, have made myself acquainted with the Reports of the Philippine Health Service for the three years 1918, 1919, and 1920, together with various other relevant publications. A corresponding report for the year 1921 has not been obtainable—possibly it has not been issued—but some partial reports have become available.

The three annual Reports contain between them over 1,400 closely packed pages of miscellaneous material relating to health and disease in the islands, prepared under the direction of Dr. Vicente de Jesús, Director of Health. At the end of each there is a superabundantly long index, bewildering in its details, repetitions, and omissions, but the volumes are not prefixed by any table of contents to guide the reader in search of information. Some of the contributions are evidently by officers to whom English is a foreign language; they are not in the least to blame for that, but the meaning is occasionally obscure, and these matters are mentioned only lest the reviewer may anywhere have fallen into error. The reports have received attention in America and this country owing to their remarkable statistics of small-pox and vaccination. In reply to a question in Parliament Sir Alfred Mond, then Minister of Health, gave the following figures<sup>1</sup> of small-pox cases and deaths in the Philippines:

Year.	Cases.	Deaths.
1915 ... ..	6,265	216
1916 ... ..	2,520	554
1917 ... ..	542	255
1918 ... ..	47,363	16,447
1919 ... ..	65,180	41,408
1920 ... ..	10,448	4,386
1921 ... ..	1,823	790

*Population.*—By summation from different parts of the reports of figures which are not given in any one place, the population of the islands appears to be as follows:

(1) 1919 Report, p. 101, Provinces ... ..	8,934,448
(2) 1920 Report, p. 367, Manila ... ..	289,463
(3) 1920 Report, pp. 457-8, Mindanao and Sulu ... ..	512,907
	9,736,818

Luzon, the principal and most northerly island, contains the capital, Manila. Mindanao and Sulu are southern islands. There are thirty-six provinces in the northern islands and nine in the southern, but I take it, though the point is not clear, that the population under (1) above does not include that of the nine southern provinces, which I have added under (3). The Governor-General of the Philippines, Major-General Leonard Wood, M.D., in May, 1922, estimated the population at approximately 11,000,000.<sup>2</sup> The whole group of islands is situated south of China, east of Siam, and north of Australia. The temperature ranges from 90° to 100°.

After the war with Spain in 1898 the United States came into occupation of the Philippines, and in July, 1901, the military government was formally succeeded by the civil.<sup>3</sup> At the end of 1918 the Filipinos themselves took over entire charge, but transfer of control appears to have been in progress for some time previously.

It will be convenient to discuss the subject in respect first of small-pox and next of vaccination.

## I. SMALL-POX.

Small-pox is endemic in the Philippines. It is stated, on responsible authority,<sup>4</sup> "that during the Spanish régime and for some years after the American occupation more than 40,000 deaths from small-pox occurred annually in the Philippines."

In the Report for 1920 (diagram opposite page 216) the following small-pox statistics appear:

Small-pox.			
Year.	Deaths.	Year.	Deaths.
1932 ... ..	14,795	1912 ... ..	561
1933 ... ..	18,919	1913 ... ..	853
1934 ... ..	9,308	1914 ... ..	322
1935 ... ..	5,055	1915 ... ..	257
1936 ... ..	4,044	1916 ... ..	239
1937 ... ..	2,604	1917 ... ..	785
1938 ... ..	7,810	1918 ... ..	14,574
1939 ... ..	5,363	1919 ... ..	45,873
1910 ... ..	3,106	1920 ... ..	4,386
1911 ... ..	1,106		

It will be seen that the figures for the years 1915-20 have a general resemblance to those given by Sir Alfred Mond, but are not identical with them. While the disease is obviously endemic, the figures suggest that for a number of years prior to the epidemic of 1918-20 many provinces or islands may have had no small-pox, and in no year save 1919 is any approach made to the mortality of 40,000 said to have occurred under Spanish rule.

*Fatality.*

Following Sir Alfred Mond's figures, the percentage fatality in each of the seven years 1915-21 was 3, 22, 47, 34, 68, 42, and 43. With the exception of the first two, these rates are remarkably high, especially as they include both vaccinated and unvaccinated. But before accepting them certain points must be considered.

*Varioloid* in the Reports is often classed separately from variola, and shows a much lower fatality rate. In Manila (Report, 1918, p. 283) there were 1,326 cases of small-pox, with 66 per cent. of deaths, but besides there were 521 cases of varioloid with 11 deaths, or 2 per cent. In the same city in 1919 (p. 79), of 57 small-pox cases, 37 were fatal, but of 29 varioloid cases only one died. San Lazaro Hospital for infectious diseases has separate departments for small-pox and varioloid, as well as for varicella. In 1918 (p. 54) the hospital had 1,079 cases of small-pox with 528 deaths, whilst in 160 cases of varioloid there were only 11 deaths, and in 1919 (p. 37), though the numbers were quite small, the same kind of difference is recorded. These proportions are not maintained everywhere. In the southern islands in 1919 (p. 356) there were only 102 varioloid cases with 7 deaths, against 5,840 cases of small-pox with 1,466 deaths. It would appear, therefore, that here practically all variolous cases were entered as small-pox, and it is very notable that the fatality rate of 25 per cent. is much lower than the rates above given for Manila and San Lazaro Hospital.

Apart from statistics references to varioloid are few. Dr. Eugenio Hernandez, chief of the Division of the Provinces, says (1918, p. 116):

"Both virulent and mild small-pox types of the disease have been present during the epidemic. All cases of haemorrhagic type were fatal. Mild cases ... .. the latter the form was generally discrete small-pox or mild varioloid."

This is in accord with President Taft's reference, in an address to the Medical Club of Philadelphia in 1911, to the Philippines having been afflicted with "small-pox of all kinds ... in which the black small-pox of the most virulent type flourished before our coming." Of the southern islands in 1919 Dr. Jacobo Fajardo, Chief of Division, says (p. 355) that the varioloid fatality rate was 6.96 per cent. (102 cases with 7 deaths), and that:

"The majority of the cases were persons who had been vaccinated, but with negative results, although there were some cases with positive vaccination."

Apart from these observations, there is no explanation of how the word "varioloid" is applied, whether in the old sense of variola modified by vaccination; or to a mild type of small-pox breeding true, but running concurrently with the haemorrhagic sort; or whether the name was given to the milder cases of a common epidemic. But the existence of varioloid was looked on as a reason for pressing the practice of vaccination, and its separate classification seriously affects the value of the fatality rates.

*Domestic Treatment of Small-pox.*

Another question bearing on the fatality rates is the kind of service, medical and nursing, available in the Philippines. In 1919 (p. 192), in the Provinces 288 emergency hospitals,

<sup>1</sup> The Fight against Disease. April, 1922. Research Defence Society; Macmillan and Co.

<sup>2</sup> U.S. Public Health Service Weekly Report, September 22nd, 1922.  
<sup>3</sup> Philippine Journal of Science, vol. iii, September, 1928, p. 270.  
<sup>4</sup> Victor G. Heiser, M.D., Consultant in Health to the Governor-General of the Philippine Islands, and Charles M. Leach, M.D., Manila (Journal of the American Health Association, July 1st, 1922, p. 401).

including about 100 isolation houses, were established, and among 16,743 cases of small-pox received into them there were 4,706 deaths, or 28 per cent., as against 54 per cent. in cases treated at home. In 1920 (p. 226) 21 emergency hospitals were established in the Provinces, and the fatality rate in them was only 16.8 per cent., against 43.5 per cent. outside. There appear to be about 1,200 physicians and surgeons in the islands and 1,100 trained nurses,<sup>6</sup> or one doctor and one nurse to about 8,000 of population. In the public service (1919, p. 104) there is a doctor for every 34,440 inhabitants, and a nurse for every 69,414, "considering that midwives and dispensary attendants may perform the work proper of the nurses."

"The people themselves who have this meagre public and private medical and nursing service were described by Dr. Heiser when Director of Health" as "a weak and feeble race," "superstitious, content in ignorance and poverty, with habits "the antithesis of the simplest health doctrines and practices." Some fifty dialects are spoken by peasants who understand neither English nor Spanish. With such a population unskilled in mothercraft and in nursing and dieting of the sick, and very poorly provided with doctors and nurses, it is not surprising that the small-pox fatality rate of cases left at home was double that of the hospitals.

#### Notification.

A third question bearing on the fatality rate is the completeness or incompleteness of notification of the disease. Fatal cases would almost necessarily be known in connexion with death and burial, but mild cases might not be reported. "Many babies suffering from small-pox were concealed, and not discovered till the disease was well advanced" (1918 Report, p. 123, Provinces). Little reference, however, is made to the matter. The word "notification" does not occur in the index of any of the volumes. Any extensive evasion of intimation would misrepresent the facts in two respects—by understating prevalence and overstating fatality.

While the above considerations as to varioloid, domestic treatment, and notification compel the view that for purposes of comparison the fatality rates are far too high, they do not suggest what should be substituted for them; they, however, leave no doubt that small-pox in the Philippines has been a very fatal disease.

#### Epidemic Virulence.

It is of epidemiological interest to observe the increasing virulence of the disease from the beginnings of the recent epidemic until its culmination in 1919. Attention has already been called to the successive annual rates from 1915 to 1920, but that is not all. In the Report for 1918 (p. 7) the Director of Health notes that, although small-pox was reported in 1916 and 1917 from certain provinces, the other provinces and the city of Manila still enjoyed immunity.

"For the last two years, however," he says, "a notable increase in cases of varioloid had been noted, and this Service had pointed out that the immunity conferred to the population by the previous general vaccination had begun to wane."

Dr. Rosario, in reporting on Manila (1919, p. 78) makes a similar observation regarding variola. The small-pox epidemic began there in December, 1917, and was the first after nine years.

"The fatality rate had "been observed to be increasing from 10 per cent. in the former years, 16.13 in 1905-6, 25 to 50 per cent. in 1907-8 in the whole Philippine Islands, and 65.51 during the present epidemic."

#### II. VACCINATION.

An immense amount of vaccination has been reported in the Philippines since the islands came under the control of the United States.

There are references to general vaccinations in 1935-6 (1918 Report, p. 7) and in 1939-10 (1919 Report, p. 134). In a report belonging to the third quarter of 1907, issued by the Bureau of Health, Dr. Heiser states that more than two million persons had been vaccinated, and "in about another year it is hoped that the first complete primary vaccination ever attempted will be completed." In 1919 (p. 197) it is said that "more than ten million persons had been vaccinated, which constitutes more than the population corresponding to this division" (the Provinces). In 1920 (p. 260), owing to revaccination having been begun, the total number of persons vaccinated in the Provinces in the three years 1918-20 is stated at 13,699,974.

These vaccinations were in the course of, not before, the epidemic, but from 1914 to 1917 in the quarterly reports

<sup>6</sup> Public Health Reports issued by the U.S. Public Health Service, Washington, vol. 37, No. 38, September 22nd, 1922.

<sup>7</sup> Philippine Journal of Science, vol. v, 1910, p. 17a.

very many thousands of vaccinations, even hundreds of thousands in some quarters, were alleged to have been performed. The word "alleged" is used advisedly.

I proceed now to make some observations on vaccination in the Philippines as revealed in the Reports and otherwise.

#### The Attitude of the Filipinos.

Dr. D. A. Jugueta, chief of one of the vaccinating parties to be referred to later, writes (1919 Report, p. 217):

"Lack of co-operation on the part of a great many people as the result of ignorance and superstition constitutes the most serious drawback in the general vaccination." In the Provinces "a great many of these people show antagonistic spirit towards the work, and not only avoid vaccination when they can but often try to hinder the work of the party." Further, "a great many of them prevent the successful taking of the vaccine."

The last point will be mentioned again in relation to the island of Cebu.

#### Inefficiency of Vaccination Service.

The Reports contain much evidence and many complaints of the inefficiency of the service, and the incompetence, carelessness, and untrustworthiness of the local officers. Whoever was responsible for central supervision, whether United States or Filipino officers, it is important to bear in mind that for local service only the latter were available. Dr. Eugenio Hernando, chief of the division of the Provinces, in describing the organization of his department at the beginning of his report for 1919 attributes low efficiency to two main causes:

1. The small number of employees compared with the population.

2. "Because many of the sanitary inspectors are practically inefficient to discharge the duties as such; however, they are retained in the service for lack of better ones." About 90 per cent. of them were not classified in the Civil Service, and the standard of salaries did not attract better men. In 1920 (p. 19) Dr. Vicente de Jesus writes that "the lack of properly trained personnel is being keenly felt, especially outside of Manila"; in these outside areas even a not sufficiently attractive. Dr. Jaco southern division, writes in 1920 (p. 312) concerning Misamis of "the lack of instructions by the district health officer of said province to the sanitary inspectors and vaccinators, and the lack of supervision by him of their work."

Dr. J. D. Long (who succeeded Dr. Heiser as Director of Health) doubted, in February, 1918 (p. 193 of 1919 Report), whether annual systematic vaccination had been carried out, or that in certain localities the inhabitants had remained unvaccinated. In a circular to all district health officers in April he says that "it appears that some district health officers do not take the proper interest in a sanitary measure so necessary to protect the community," and he threatens severe punishment for negligence. A few months later (p. 195) he writes that, especially in the case of recalcitrant well-to-do persons, the necessary efforts are not made to carry out the provisions for vaccination.

Complaints of inefficient service are not confined to the prevention of small-pox. Concerning an epidemic of dysentery (1919 Report, p. 192) it is recorded that:

"The attention given by some of the health officers was so very little that" an admonitory circular was issued in July, 1919, stating "that district health officers and presidents of sanitary divisions are not paying due attention for the control of the said disease."

#### Falsification of Returns.

In the Report for 1919 on the Provinces (p. 204) it is complained by Dr. Hernando that:

"Sometimes reports are received stating that systematic vaccination has been completed in a certain municipality, and this appears to be true upon consulting the reports of vaccinators, but on several occasions a personal inspection in the municipality concerned disclosed the fact that 20 to 30 per cent. of the children were never vaccinated."

The volume for 1920 (p. 312) gives an illustration of this in the southern islands.

"In the reports of the district health officer it appears that 250,000 vaccinations were made, but subsequent investigations revealed that only 131,700 were performed."

This goes far to support the view vigorously expressed by Major General Leonard Wood, Governor-General of the Philippines, in April, 1922.<sup>8</sup>

"The record shows that vaccination has been steadily continued since 1913, but on investigation it was found that owing to the inefficient inspection vaccination consisted mostly in destroying the vaccine and submitting reports to the main office that it had been applied."

<sup>8</sup> U.S. Public Health Service Weekly Reports, September 22nd, 1922.

*Inspection of Vaccinations.*

Not nearly all alleged vaccinations were officially inspected. Of 414,410 in 1918 (p. 62) only 154,664 were seen again as to the result, though this was in Manila, where surveillances might have been assumed. In the Provinces in the same year, if the returns are to be believed, of 4,318,830 vaccinations 3,285,376 were inspected. In the southern islands the respective figures were 176,659 and 108,055. In April, 1918 (p. 194 of 1919 Report), Dr. Long pointed out that only 48 per cent. of vaccinations had been inspected. In 1919 in Manila there were recorded 360,712 vaccinations and 133,331 inspections, the corresponding figures for the Provinces (p. 476) being 7,277,481, and 4,867,646. The figures for 1920 (pp. 260 and 320) are similar, but those for Manila are notable—257,951 vaccinations and only 83,007 inspections.

These figures are quoted, not in criticism of the administration, for whom complete inspection may have been an impossible task, but only to emphasize the fact that as to millions of persons returned as vaccinated it is not professed that anything whatever is known as to success or failure.

*Negative Vaccinations.*

Where vaccinations actually were inspected the percentages of failures were extraordinarily high.

In the Provinces (1920 Report) in two and a half years from the middle of 1918, about 4,300,000 vaccine units "had been distributed" with an "estimated positive result of 77 per cent." In the year 1920 itself the total vaccinations (included in the two and a half years) were 3,222,460, of which 1,399,985 were successful, or 65.58 per cent. In the southern islands (1919 Report, p. 357) the positive results were 57.22 in 1918 and 64.93 in 1919, but sometimes they were only 10 to 15 per cent. (1920 Report, p. 24). In the Provinces the failure rate that year ranged from 21 to 78 per cent. in different provinces. In 1919 the figures were generally similar. In April, 1918, Dr. Long complained (p. 194 of 1919 Report) that the percentage of positive results was much less in the Provinces than in Manila. In 1919 (p. 476 and up to February, 1920, the total vaccinations for Manila and the Provinces were reported as 7,638,195, the inspections 5,000,974, the positives 3,310,932, and the negatives 1,690,045, or 33 per cent. In the following year, for the same areas (p. 418), the returns gave vaccinations 3,525,749, inspections 2,518,861, positives 1,468,944, and negatives 849,917, or over 36 per cent.

These figures, however, include all ages, and revaccinations as well as primary vaccinations, so it has to be considered whether much or all of the failure was not due to insusceptibility through previous vaccination. That explanation is advanced regarding Manila, where, of 154,644 vaccinations in 1918, no fewer than 85,085, or 55 per cent., were negative. Unfortunately its validity is very limited, as proved by the statistics of negative results in children under 1 year, where protection by previous vaccination would be negligible. In the capital, where, if anywhere, it might be expected that competent vaccinators would be available and lymph deterioration avoidable, there were 23,058 vaccinations of babies under 1 year in 1920. The results were inspected in 16,045 of these, and in the total inspected there were 26.6 per cent. of failures. The details are as follow:

Age.	Inspected.	Positive.	Per cent. Positive.
1-2 months...	9,768	7,461	76.38
2-3 " "	3,614	2,468	68.28
3-6 " "	2,335	1,621	69.42
6-12 " "	328	242	73.78

There is still, however, another possible explanation of failures under 1 year of age. Dr. Dalmacio A. Jugueta (1919 Report, p. 217), who had charge of a vaccinating party (to be referred to later) in the island of Cebu, gives the following percentage of positive results at different ages:

	Per cent.
From 0 to 1 month ...	59
" 1 month to 1 year ...	64
" 1 year to 5 years ...	66
" 5 to 10 years ...	59
" 10 to 20 years ...	56
Over 20 years ...	61

The failure rates therefore ranged from 34 to 44 per cent. Among infants they were 41 per cent. under 1 month and 36 per cent. between 1 month and 1 year. About infants Dr. Jugueta says:

"There are only a few mothers who are convinced and are willing to submit their babies to the vaccination, and since they only have them vaccinated to evade the law a great many of them prevent the successful taking of the vaccine, and thus the low rate of percentage of positives."

This is a relevant consideration, and may account in whole or in part for the percentage of failures being considerably

higher in Cebu than in Manila. But it is to be noted (1919 Report, p. 209) that only after three failures is a result to be recorded as negative.

For Manila of every 100 ultimately positive, 73 were so at the first attempt, 17 at the second, 6 at the third, and 4 after a fourth or further vaccination. On the whole the large proportion of ultimate failures in both Manila and the Provinces seems to point pretty definitely to inert lymph or incompetent vaccination. In the 1919 Report (p. 207) it is stated that "the percentage of positives among the groups by ages from 0 to 10 years cannot be given exactly, but it is estimated by several district health officers to be 80 per cent. of those who had never been vaccinated," as against a 60 per cent. average of positives. The 20 per cent. failure in the case of unvaccinated children once more suggests inert vaccine.

*The Vaccine used in the Philippines.*

Drs. Ashburn, Vidder, and Gentry state, on the authority of Dr. Ruediger, in charge of the serum laboratory, Bureau of Science, Manila, which is responsible for the supply of vaccine, that the strain of vaccine virus used at that time (1913) "was derived from a fatal case of human small-pox in 1908, having been passed first through monkeys, and from the second monkey to a heifer, and from the fifth heifer to man." Whether this lymph is still in use, or whether any fresh sources have been introduced, does not appear from the reports I have consulted. Vaccine, whatever its origin, is very likely to deteriorate in the Philippines. The temperature commonly ranges between 90° and 100° F. To many parts of the islands the distances are great, the roads and means of conveyance bad, equipment for preservation of lymph by storage in ice defective or wanting (1919 Report, p. 357), and the staff ignorant, indifferent, and inefficient.

Concerning its use in practice, I again resort to quotation:

Dr. Jacobo Fajardo, chief of the division of Mindanao and Sulu (the southern islands), says in the Report for 1918 (p. 211) that one of his difficulties was the "insufficiency and unsatisfactory kind of vaccine virus," and that as regards the Mohammedan population "after preaching the efficacy of vaccination against small-pox they allowed themselves to be vaccinated. With the virus supplied the vaccination did not prevent or attenuate the small-pox epidemic." Concerning an outbreak in Lanao, where there were 2,700 cases, he writes: "It would not have spread throughout the province were it not for the inactivity, or at least the weakness, of the vaccine virus."

Dr. Vicente de Jesús, who followed Dr. John D. Long as Director of Health, speaks in the 1920 Report of cases occurring "in the most remote barrios where vaccine virus could not arrive in good condition, but by the use of powdered dry vaccine in such places" the number of cases of small-pox was much reduced. In the same Report (1920) Dr. Fajardo is no less emphatic than in 1918. Concerning Misamis he writes: "The lack of instructions by the district health officer of said province to the sanitary inspectors and vaccinators, and the lack of supervision by him of their work, account in great measure for the unchecked spread of the disease."

It was here that the vaccine gave only 10 to 15 per cent. of positive results, notwithstanding resort to thermos bottles, banana leaves, etc., in substitution for ice. Dried vaccine, however, gave good results, but unfortunately the Bureau of Science "at best could fill only about 25 per cent. of the requisitions."

Suspicion arises as to the value of the vaccine used, even in the capital city of Manila.

Dr. Heiser (who, after ceasing to be Director became Consultant in Health to the Governor-General of the Philippines) and Dr. Charles M. Leach of Manila have stated recently that the successfully vaccinated in Manila were immensely better off than the others, in respect both of attacks and deaths, and there need be no doubt that even poor lymph was of great value compared with no vaccination at all. But the figures which challenge attention are those relating to attacks and deaths amongst vaccinated infants and children. Under 1 year of age there were ten attacks and four deaths; between 1 and 2 years twenty-one attacks and fourteen deaths; between 2 and 3 years ten attacks and three deaths; between 3 and 4 years eighteen attacks and eight deaths; and between 4 and 5 years twenty-one attacks and nine deaths. These figures in respect both of attacks and deaths are frankly impossible in the case of anything that in this country would be considered to have the remotest claim to be called successful vaccination.

*Duration of Vaccinal Protection.*

In a circular of instructions to district health officers issued on February 25th, 1918 (p. 193 of 1919 Report), Dr. John D. Long requested that, excluding children under 2 years of age who had at any time been vaccinated with

positive results, "all other persons should be revaccinated even though they have been vaccinated in former years with positive results, except those successfully vaccinated during 1917." Looking to the date of the circular, this instruction means in effect that the authorities could not rely on much more than a single year's protection from a vaccination as performed in the Philippines. On the same point reference may be made to an article<sup>9</sup> by Dr. Heiser in 1910, which shows that the difficulty about the shortness of immunity was no after-thought to account for the epidemic of 1918-20. At a time when the annual deaths from small-pox had fallen from 40,000 before and in the early days of the American occupation, and from the 14,000 of 1902 and the 19,000 of 1903 to 3,000 in 1910, Dr. Heiser, then Director of Health, said he had found that ordinary cow-pox was not as effective among dark as among white-skinned races. Among 100 vaccinated whites no case had occurred within five years after vaccination, whilst among Filipinos, "of whose successful vaccination within one preceding year there could be little doubt," many cases had occurred. Experience at Bilibid Prison supported this view. He was also careful to point out the position as regards lymph supply, especially for remote regions. Lymph would not keep for more than seven to ten days, whilst powdered vaccine and dry points had been tried with only (at that time) a small measure of success.

As regards the shortness of immunity conferred on natives by vaccination, one statement to the contrary requires to be mentioned. In the 1919 Report (p. 206) Dr. de Jesus writes:

"Many mothers who have been confined in small-pox hospitals with their children sick of small-pox were only once vaccinated, but vaccinated well, and not one of them developed infection of small-pox in spite of the great exposure to which they had been exposed."

Such immunity is often experienced in this country, but admission to hospital of a mother in such circumstances would depend on the recency of her vaccination or on her submitting to revaccination. Only if different vaccines of different value were in use, or if types of small-pox were totally different, can these statements of Dr. Heiser and Dr. de Jesus be reconciled.

In the 1919 Report (p. 193) it is stated, regarding the epidemic up to that time, that of 56,018 reported cases, 52,763, or 94 per cent., had never been vaccinated.

#### *Dried Vaccine.*

The prospects as regards remote regions are now better. The 1919 Report of the Health Service (p. 205) quotes an important report by the director of the Bureau regarding the preparation of dried and pulverized vaccine in the later part of 1919. Experiments were not finished by December 1st (the date of the report), but good results were being obtained.

"The vaccine showed first-class takes after being prepared and kept without ice for two months at room temperature." A parcel prepared on September 20th was shipped on November 1st by a boat which returned to Manila on November 24th. On the following day the lymph was tested on monkeys and showed first-class "takes" after having made a forty-day trip round practically the entire archipelago.

#### *A New Vaccination Scheme.*

While struggling with all their difficulties and disappointments, the Health Service is redoubling its efforts to rid the islands of small-pox. In 1919 (pp. 207-218) a new organization was established for "systematic and extensive vaccination throughout the islands and to obtain complete immunization of all the inhabitants for the next eight years." The scheme is twofold: first, "vaccination of all newborn and contacts of small-pox cases," and secondly, "intensive and extensive vaccination of all the inhabitants never vaccinated, or vaccinated with negative results, or vaccinated eight years ago." For the former purpose the regular and temporary sanitary personnel assigned to the provinces is relied on. For the second, six special vaccinating parties were organized to work independently of the regular staff. Each of the six parties consists of twenty vaccinators, with a doctor as chief. Three of the parties were allocated to Luzon and three to more southern provinces or islands. The vaccinators were given full written instructions, which, as the Report shows, were carefully prepared. But whether owing to inert vaccine or to habitual wiping away of lymph immediately after its insertion, as already described by Dr. Jugueta, or to insusceptibility due to previous vaccination, or to these

causes combined, the efforts of the vaccinating parties, as measured by case success, were far from reassuring. (It may be interpolated here that in this country Government lymph in the hands of public vaccinators has a case success of 99 per cent. and an insertion success of 96 per cent.)

A tabulation of the work done shows that in 1919, in 75 municipalities, with a total population of 800,495, there were performed 398,753 vaccinations, of which 145,551, or rather less than half, gave a positive result. In 1920 more than double the amount of work was overtaken. In 116 municipalities, with a population of 1,161,391, there were 550,855 vaccinations, with 345,366, or 36 per cent., of positive results.

The instruction is that no case shall be reported as negative excepting after three failures. No locality is to be considered "completely and positively vaccinated unless the total positives equal at least 75 per cent. of the total population."

But the statistics show that not one of the six parties succeeded, either in 1919 or 1920, in achieving anything like 75 per cent. of successes. Insusceptibility to vaccination owing to previous small-pox was only to be recognized as a reason for not vaccinating if the attack had occurred "during the preceding year"; that should account for some proportion of the failures.

It surely cannot be doubted that the members of the six vaccinating parties have, after all the past experiences in the Philippines, been sufficiently instructed in their work, and that its performance is being medically supervised. The regulations issued for vaccinators show that lymph conveyance and preservation are now receiving much attention. Portable ice boxes, we are told, are to be regularly used, and vaccinators are warned against exposure of the vaccine to the sun, or keeping it in the pocket of the operator. Dried lymph is being provided for remote districts. Even, however, if 100 per cent. of positive results were obtained from dried lymph, a question behind it all would be the efficacy of the lymph used in the Philippines against the strain of variola locally endemic.

#### *Manila in 1918.*

But to whatever degree the efficacy of the vaccine in use falls short, it is right to call attention to evidence by Drs. Heiser and Leach that where it gets a fair chance it is of real value in diminishing the risk both of attack and death. Drs. Heiser and Leach, in the paper already referred to, give various particulars regarding the prevalence of small-pox in Manila, where the disease could be kept under skilled observation. Of 1,326 cases in 1918, only 177 occurred among the successfully vaccinated, and of 999 deaths only 60, or 7 per cent., were in that class. In the city not a death had occurred from small-pox in the seven years prior to 1914, and in the population of the Philippines generally, instead of 40,000 deaths a year, there were only a few hundreds. But, they say:

"After 1914 general vaccination of newborn children and other unprotected persons was not effectively carried out," and "much of the vaccine was never applied or not until it had deteriorated. Minor health officials and vaccinators found it much easier simply to report vaccinations than actually to carry out the procedure. Quantities of vaccine virus were actually discovered in waste-paper baskets. . . ."

"Thus a huge unvaccinated population came into being, and it was only necessary for the ever-present spark to fall among them to start the conflagration."

When small-pox did come to Manila in 1918, no less than 67 per cent. of the cases and 75 per cent. of the deaths occurred in children under 4 years of age—that is, born since the practice of vaccination had been neglected, as explained by Drs. Heiser and Leach. But even so the attacks and deaths which they record amongst vaccinated babies are occurrences which ought to be unknown.

#### *SUMMARY.*

The available data appear to warrant the following provisional conclusions:

1. Small-pox in the Philippines is very severe in type, but its natural fatality rates are very considerably overstated by the exclusion of varioloid, the want of skilled treatment and nursing in the homes of the people, and, probably, incomplete notification of cases.
2. The published statistics of vaccination in the Philippines are quite unreliable owing to (a) domestic resistance to the operation, (b) inefficiency of the service, (c) falsification of returns, (d) insufficiency of inspection, and (e) the high percentage of negative results in inspected cases, even in infants.
3. The vaccine which has been used in the Philippines is subject to deterioration owing to climatic conditions, defective

<sup>9</sup> Unsolved Problems Peculiar to the Philippines, *Philippine Journal of Science*, vol. v, 1910, p. 174.

preservation and transit, and want of care by local officers. At least part of it appears to be inefficient or inert.

Much in this article has been said by way of raising questions rather than of stating conclusions, and much remains obscure which ought to be made clear as respects both small-pox and vaccination. From the point of view of epidemiology it is desirable to know what more may be ascertainable of the history of small-pox in the Philippines—its prevalence, its varieties, from black pox to varioloid, its fatality in the days of the Spanish possession and when the United States came into control. But the United States Public Health Service appears to be no longer responsible, the Filipino local government having taken over the administrative control. The whole subject calls for inquiry—not merely by study of the Reports, as in this article, but by competent visitation of the islands and skilled investigation of every essential detail. One body, the Rockefeller Foundation, seems in every respect qualified for the duty. It recently carried out through a specialist an examination of the health problems of Mauritius, a British possession much smaller and less important than the Philippines. The Rockefeller Foundation had already, in May last, entered on a medical survey of the Philippines, and though the Governor-General in mentioning this gives no details, yet it may be assumed that small-pox and vaccination must come under review.

## ANTHRAX CONTROL.

### INTERNATIONAL ADVISORY COMMITTEE.

We have received from the headquarters in Geneva of the International Labour Office, League of Nations, an account of the first session of the International Anthrax Committee held in London from December 5th to 14th, 1922.

The Committee was set up by the Third International Labour Conference with a view to studying thoroughly the problem of industrial anthrax, and more especially that of disinfection in the wool industry.

The Committee, which was to include experts appointed by the various importing and exporting countries, was composed as follows:

Australia, Sir Thomas Oliver; Belgium, Dr. Glibert; France, M. Boulin; Germany, Dr. Frey; Great Britain, Sir Wm. Middlebrook, Chairman of the Departmental Committee on Anthrax; Italy, Dr. Loriga; India, Colonel Hutchinson; Japan, Dr. Kawai; South Africa, Dr. Dixon; Spain, Professor Roca; Sweden, Mr. Ribbing; Observer for the United States, Dr. Dorset.

The Committee was charged with the duty of inquiring into:

1. The problem, in all its bearings, of the disinfection of wool and hair suspected of being infected by anthrax.
2. The most practical and effective methods of preventing infection among flocks.
3. To submit a report to the Governing Body in sufficient time to allow the latter to decide upon the necessity of including the question in the agenda of the Fifth International Labour Conference.
4. The possibilities of dealing with infection by anthrax from hides, skins, and other suspected animal products.

The preliminary work of the Advisory Committee was summarized in a documentary report of the Industrial Hygiene Section of the International Labour Office containing information from twenty-seven countries as to statistics and legislation regarding the danger of anthrax among human beings and animals. The report also contained an analytical chapter on disinfecting methods proposed and measures contemplated to combat the diseases among animals. Moreover, the Chairman of the Committee, Sir Wm. Middlebrook, distributed a pamphlet containing a brief survey on the development of the question and the results obtained in England during the last few years.

After full discussion the following resolutions were carried:

1. That hair used in the brush-making and upholstering industries shall be disinfected before the materials are handled industrially.
2. That wool and hair to be used in the textile industry shall be disinfected before the materials are handled industrially, except in the following cases:
  - (a) If the country of origin is included in the schedule of countries where the danger is slight.
  - (b) If the material to be imported has already been disinfected by a process recognized as effective.
  - (c) If wools and long hair have to be sorted before washing, unless these products are not included in the list of harmless products.
  - (d) In such other cases as may be determined by the Committee.

The experts who had come to give evidence at the request of certain members of the Committee agreed that the proportion of wool imported into England which does not require sorting before washing is extremely small, and that it is almost always this kind of goods which gives rise to the danger of anthrax amongst the workers; that if it is technically possible to sort the wools after washing, it would be bad from the commercial point of view. The list of countries where the danger is slight will be brought up to date each year by the Advisory Committee on Industrial Hygiene of the International Labour Office. In the same way the industrial processes of disinfection will have to be approved by the Governing Body of the International Labour Office in accordance with the opinion of the Advisory Committee on Industrial Hygiene, and eventually approved by the Health Committee of the League of Nations.

The Committee was of opinion that the best precautions against the spread of anthrax among flocks are at the present

1. Compulsory notification and official verification of cases of anthrax.
2. Inoculation of animals suffering from or suspected of suffering from anthrax.
3. Destruction of the entire carcass of any animals dead or suspected to have died from anthrax, and disinfection of the immediate surroundings of the place where the animal has died, as well as of the premises where it has been kept.
4. Preventive inoculation of animals against anthrax.

In regard to industrial anthrax generally the Committee adopted the following resolution:

The Committee is of opinion that in most countries the principal danger of industrial anthrax arises in the manipulation of hides and skins, and recognizes the impossibility of securing at the present time complete disinfection to protect against this danger. The Committee therefore recommends that regulations be laid down in the different countries having for their object the protection of the workers and the soil against infection by anthrax from hides and skins.

The Committee further suggests that the International Labour Office, in conjunction with the Health Committee of the League of Nations, should organize international research and invite nations and organizations chiefly interested to undertake such research in their respective countries. The Committee considers that in view of the fact that all countries using infected materials will benefit by the discovery of a satisfactory process of disinfection it is desirable that the governing body should take into consideration the possibility of finding grants in aid of research undertaken for that purpose.

The report concludes with some observations regarding the disinfection of horns, hoofs, and bones.

## ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on January 9th 17 cases were considered and £250 voted to 13 applicants. The following is a summary of some of the cases relieved:

M.D. Brax., I.S.A., aged 62, married. Owing to chronic neurasthenia, bronchitis, and general weakness is unable to concentrate on work. Voted £26 in twelve instalments towards board and lodging.

M.D. Dublin, aged 61, married. Owing to severe nephritis with general arterio-sclerosis, has been unable to attend properly to his practice, and is now reduced to a small panel bringing in 5s. a week and private practice about the same amount. Voted £26 in twelve instalments.

Widow, aged 50, of M.D. Edin. who died in 1906. Applicant used to take rest as companion-help, but owing to ill health has had to give this up. The Guild has been helping to the extent of 5s. a week, and the Fund has now voted £12. Relieved five times, total £45.

Widow, aged 41, of M.R.C.S. Eng. who died in 1914. Owing to ill health applicant is dependent upon her mother, with whom she lives. Has been relieved by the Fund eight times to the extent of £103. Voted £18 in twelve instalments.

Daughter, aged 63, of F.R.C.S. who died in 1885. Through ill health has had to give up her profession as nurse. Only income £48 per annum, out of which she has to pay £26 for rent. Relieved twice before by the Fund, total £29; voted £18 in twelve instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed in these days of exorbitant prices for clothing and household necessities with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

A SPECIAL number of the *Zeitschrift für Hygiene und Infektionskrankheiten* has been dedicated to the bacteriologist Flüge, on the occasion of his 75th birthday, and a Flüge fund has been raised for the scientific investigation of tuberculosis.

# British Medical Journal.

SATURDAY, JANUARY 27TH, 1923.

## EDWARD JENNER.

It is a hundred years since the remains of Edward Jenner were laid to rest in a vault in the chancel of Berkeley Church. He died on January 26th, 1823, and was buried on February 3rd. He had been born in 1749 in the vicarage of Berkeley, and spent a large part of his professional life in his native village as a general practitioner—one of the most illustrious who has ever adorned the ranks of medicine. His great teacher and friend, John Hunter, wanted him to enter on a different career; but Jenner was a born naturalist, fond of a country life, so that even when, in the interests of vaccination, he was persuaded to take a house in London, he quickly repented, and later on returned to Berkeley.

The oft-told story of his great conception of preventing small-pox by means of cow-pox is classical in its simplicity and brevity. In his master's surgery at Sodbury he heard a countrywoman remark that she could not take small-pox because she had already had cow-pox. The little incident remained in the mind of the busy village doctor for many years, to be mused over, discussed with friends lay and medical, set aside and returned to with a curious mixture of perseverance and dilatoriness which was no doubt in his mind when he remarked in his *Inquiry* that people may not be aware "how often men engaged in professional pursuits are liable to interruptions which disappoint them almost at the instant of their being accomplished." Ultimately, however, in 1796, he put the matter to the touch—he inoculated with cow-pox, tested the effect by inoculation with small-pox, and found that immunity had been achieved. The rest of his life was devoted mainly to the promotion of vaccination.

Until after the end of the seventeenth century an attack of the disease itself was the only means of acquiring protection against small-pox. The price paid for this protection of survivors consisted in the death of those who did not survive, and disfigurement, blindness, and ill health amongst those who were not slain by the pestilence. But during the last three quarters of the eighteenth century the cost was lower to such as resorted to small-pox inoculation, though it is doubtful whether on balance inoculation did not do about as much harm by spreading the infection as it did good by protecting those who were inoculated. Then, at the end of that century, Jenner introduced vaccination, which protected the individual and was accompanied by no risk of conveying small-pox to others. Thus salvation was offered from the most terrible scourge which at that time afflicted humanity, and Jenner was directly responsible for saving more lives and averting more misery than it had fallen to the lot of any single human being to accomplish from the dawn of history to his day.

Jenner published his *Inquiry* in 1798, issued *Further Observations* in 1799, and *A Continuation of Facts and Observations* in 1800, besides various short papers in the *Medical and Physical Journal*; he wrote also an infinity of letters to correspondents. Briefly he held that the teats and udders of cows were subject to various eruptions, of which only one was the true cow-pox; that it was derived from an eruptive disease of the horse; that cow-pox was without general eruption and its accompanying infection; that the local vesications on the hands of dairy maids accidentally inoculated from cows

had a surrounding areola, and so were like a pearl on a rose leaf; that the axillary glands became affected, but that any indisposition accompanying the casual disease was due, not to the vaccine virus, but to subsequent irritation and inflammation, and was therefore accidental, not essential; that matter for inoculation, whether of small-pox, horse-pox, or cow-pox, should be used before becoming purulent, otherwise it might be specifically ineffective; and that when variolous matter was taken to test the success of vaccination the same rule should be observed.

Jenner was quite wrong about horse-pox (or horse-grease) being the only source of vaccinia, but the question was of no essential importance. In the present day Dr. Monckton Copeman, looking to the difficulties experienced in direct variation of bovine animals, has advanced the interesting speculation that much of the cow-pox in the prevaccination era may have been due to the transference to cows of matter from the hands of dairymaids engaged in milking whilst suffering from the slight eruption which commonly followed small-pox inoculation.

Jenner always kept in view, as a pole-star to guide him, the conviction that cow-pox was small-pox of the cow. This was hotly disputed in his own time, but has long ago been triumphantly proved and is now universally accepted. It gave him a wonderfully complete grasp of the principles and practice of his prophylaxis. When therefore Woodville, carrying on cow-pox inoculation in the very unsafe conditions of the Small-pox Hospital, seriously endangered the whole project of vaccination by reporting that in a large number of his cases there had occurred a general pustular eruption which he set down as belonging to the phenomena of cow-pox, Jenner tersely replied, "Where variolous pustules have occurred I believe variolous matter to have occasioned them"; Woodville soon came tacitly or explicitly to admit his error. For conducting safely and effectively the practice of vaccination, Jenner evolved and emphasized his "Golden Rule" to take lymph from the arm at an early stage, before the areola had appeared. This was at first not infrequently neglected, and sometimes the same vesicle was returned to again and again for lymph supply. In America the practice was extraordinarily bad, and when Waterhouse there wrote to Jenner that he had known of a shirt-sleeve stiff with purulent discharge from a foul ulcer being cut up into small strips and sold for kine-pox, Jenner replied that he longed for a speaking trumpet to carry on the wings of the wind across the ocean the message—Take the virus before the efflorescence appears.

But his doctrine was erroneous in one important respect. To the day of his death he held that the protection afforded by vaccinia was equal in every respect, including duration, to that of variola, whether natural or inoculated. When in the course of his later years post-vaccinal small-pox not infrequently occurred, his explanation was that second attacks of small-pox itself had exceptionally happened, and that so it must be with vaccination. But in Germany, where the influence of Jenner's views was no doubt less than in his own country, the need for revaccination began to be realized, and in the armies of various States compulsory revaccination of recruits was begun so long as from eighty to ninety years ago. In this country at that time it was coming to be thought that the original stocks of lymph might have deteriorated, and Ceely, Badcock, and others, adopting the policy of return to the cow, began their well known investigations. Since that time the need for revaccination has been everywhere accepted, and, in addition, new stocks of lymph can be established whenever and wherever it may be found desirable.

In the conditions of the present day we are finding that by concentration of effort, by what may be called intensive vaccination in a threatened area, it is often possible to counteract in great measure the effects of the public apathy, which is probably to be attributed to the less alarming types of small-pox and the longer intervals between epidemics in recent decennia. The groundwork is not nearly so good as before, but consists, first, in such routine practice of infant vaccination as still remains under the weak existing law, and secondly, in the very considerable amount of re-vaccination of male adults in the war, and of the public generally whenever there is threatened prevalence of small-pox. Even yet a considerable part of the population of the country is thus immune to small-pox, and the field for its spread is correspondingly limited. Another important present-day factor is that calf lymph is available on emergency to an extent altogether impossible when only humanized lymph was in use, and when its exiguous supply depended on the weekly vaccinations of the babies in a community. Also modern public health staffs, central and local, can, putting aside if necessary almost all other work, concentrate on the search for contacts, their vaccination and surveillance, and, if vaccination be too late, their isolation in hospitals established in well isolated situations. Isolation, however, is practicable only through vaccination. In its absence the attendants on the sick, unless indeed they had already had small-pox, would be infected by the patients. In their turn these attendants would become patients, and the disease would spread in ever-widening circles. If the whole population were protected by vaccination and revaccination small-pox hospitals would be needless; in the entire absence of vaccination they would be useless. In fact, it is Jenner who has made isolation available as a handmaid to vaccination. All this emergency effort, however, cannot but be accompanied by the toll which small-pox takes from those who are infected before they resort to the protective operation. So long as visitations of small-pox continue such loss will be an inevitable penalty for personal and national neglect.

The centenary of Jenner's death follows close on that of Pasteur's birth. Their lives overlapped by a month, Pasteur having been born thirty days before Jenner died. Their life's labours were closely related. Apart from variolation with its serious disadvantages, vaccination was the first example of the operation of the principle of individual immunization. For the greater part of a century it remained an oasis in a desert, and for long there seemed no prospect of its further application. Now, however, since Pasteur brought into existence the science of bacteriology, the sphere of immunization by different methods has been wonderfully extended, and the armamentarium of preventive medicine correspondingly strengthened. In a remarkable passage in one of his books Sir John Simon wrote that "if departed great benefactors of our race could now and then look down on the harvest fields where mankind age after age is gladdened by the fruits of their labour, they would in general find themselves less remembered than perhaps their terrestrial ambitions had desired"; but, he adds, "let the noble compensation be noted that often the thoroughness of a reformer's victory is that which most makes silence of the reformer's fame. For how can men be adequately thankful for redemptions, when they have no present easy standard, no contrast between yesterday and to day by which to measure the greatness of them?" That question applies specially to the case of Jenner, but neither Jenner nor Pasteur can ever be forgotten. It was, if we recollect aright, in an address at the centenary of the death of Robert Burns that Lord Rosebery, speculating

about the duration of personal fame, prophesied that if there were every hundred years a roll call of the famous departed, the "Adsum" of Burns would sound clear and strong all down the coming time. In the much more prosaic sphere of preventive medicine and the benefactions of science, so it will be with Edward Jenner and Louis Pasteur.

### THE INFLUENCE OF PASTEUR ON MEDICINE.

It is an appropriate coincidence that the centenaries of Jenner's death and Pasteur's birth should be celebrated at practically the same time in France. That his own nation should commemorate the centenary of Pasteur's birth as an occasion for every mark of proud respect for the great medical benefactor of mankind, who was well described as "the most perfect man who has ever entered the Kingdom of Science," is natural and right. But that our French friends of the Académie de Médecine, which has a special department organized for Jennerian vaccination, should have held a formal séance in his memory on January 23rd—three days before the anniversary of Edward Jenner's death at Berkeley, Gloucestershire, in 1823—calls for an expression of our sincere appreciation of their graceful action. Not only did the lives of these two famous men follow each other without a break, but the younger by exact laboratory methods carried on and greatly extended the bearings of his senior's clinical achievement, and with the generosity of a great mind fully recognized his predecessor's work, and did perhaps even more than justice to him by perpetuating the term "vaccine" in a much wider sense than its original and etymological application. Pasteur, in concluding the address he gave to the International Congress of Medicine in London in 1881 on vaccination in relation to chicken cholera and splenic fever (anthrax), said, "I must not end without expressing the pleasure I experience in remembering that it is as a member of an international medical congress held in England that I publish these most recent results of my experiments on the vaccination of a disease perhaps more terrible for animals than is small-pox for man. I have given to the term 'vaccination' an extension which science, I hope, will accept as a just homage to the immense services rendered by one of the greatest of Englishmen, Jenner. How great to me is the happiness to be able to honour his immortal name in this noble and hospitable city of London." From the results of his work on fermentation Pasteur became convinced that each form of fermentation is specific and due to a special organism; he then went on to show that the virus of an infection can be attenuated and employed as a vaccine to produce active immunity. In this short article the influence of Pasteur on medicine may be suitably considered as a pendant to the account in our last week's issue of his influence on surgery; and accordingly, although the important bearing of the principle of the specificity of disease (in which he took so great a part) on the outlook of medicine can hardly be exaggerated, attention will be mainly directed to the influence of his work on preventive medicine.

Long before the real recognition of bacteria Jenner noticed that cow-pox protected milkmaids from a somewhat similar but far more serious disease, variola, and, as stated in the article which precedes this, by inoculating a child with lymph taken from a cow-pock on the hand of a milkmaid, put this observation into practical use. Impressed with this idea of obtaining protection from a virulent disease by the production of a similar but slight disorder, Pasteur, dealing with the isolated virus of disease and not solely with its results, set to work to find a way of attenuating

the specific micro-organisms. This he accomplished by different methods in some of the comparatively few diseases of known bacteriology: in chicken cholera by prolonged incubation, in swine fever or erysipelas (rouget) by passing the virus through other animals, and in anthrax by cultivating the bacilli at a temperature higher ( $42^{\circ}$ - $43^{\circ}$  C.) than the optimum ( $35^{\circ}$  C.). In 1881, by inoculating animals with attenuated living cultures of anthrax bacilli, protection was obtained, and to this procedure, as it followed the lines of Jenner's vaccination with calf lymph, he applied the term "vaccination." This prophylactic vaccination, employed so successfully by Pasteur in the case of anthrax, was after a long interval practised by Haffkine (1895) against cholera, and on an even more extensive scale, and with great success, in protection against enteric fever by Sir Almroth Wright (1897). He, finding experimentally that dead cultures gave a protection quite as effectual as living cultures, used them to produce immunity—an innovation that rapidly found other applications.

In his work on the protective action of attenuated virus Pasteur was enormously in advance of his time, and indeed founded the science of immunity, established its practical application in obtaining protection against disease, and opened the way to the further development of specific curative treatment. In rabies, in which, as in small-pox, the causal organism has not been isolated, Pasteur was content to act on the assumption of its presence, thus anticipating and stimulating the discovery of ultramicroscopic organisms. He introduced the system of standardized vaccines in the prevention of hydrophobia during its long latent period—usually about six weeks—between the date of the bite and the onset of symptoms. By drying the spinal cords of experimental animals dead of rabies Pasteur found that the virulence of the emulsion made from them progressively diminished, so that after fourteen days their toxic properties were lost. Subsequently it has been thought, on the basis of Hoge's therapeutic success with diluted virulent emulsions, that the process of drying alters only the quantity and not the quality of the virus. However this may be, Pasteur obtained a series of emulsions of graduated strength from spinal cords that had been dried for varying numbers of days, and by injecting successively emulsions of increasing strength into persons bitten by rabid dogs produced an active immunity so complete that the mortality in these cases has never been more than 1 per cent. According to Calmette the former mortality of persons bitten by mad dogs was as high as 47 per cent., and when the bites were on the face 80 per cent., whereas between 1886 and January 1st, 1922, out of 44,817 persons treated by Pasteur's method at the Pasteur Institute, Paris, only 150, or 3 per 1,000, have died. The Pasteur Institutes all over the civilized world tell the same tale. The treatment, however, has no effect when the symptoms of hydrophobia have appeared, and is therefore prophylactic and not curative; it is, indeed, comparable to Jennerian vaccination, which, if employed within three days of the exposure to the infection of variola, will prevent the occurrence of that disease, probably because the incubation period of vaccinia (three days) is shorter than that (ten to twelve days) of small-pox. Nevertheless this treatment in hydrophobia differed from other prophylactic vaccinations which are undertaken with the object of obtaining in a healthy person such a degree of resistance that, if and when he is exposed to infection, disease will not follow or will take a mild form. For in the case of hydrophobia it was during the natural period of incubation that the process of immunization was carried out; and, indeed, this may be regarded as a step towards the curative vaccination therapy subsequently elaborated by Sir Almroth Wright. By establishing the existence of bacterial toxins Pasteur

cleared the way for Roux and Yersin's discovery of diphtheria toxin and so for that of antitoxic serums.

To Pasteur medicine, and particularly its real aim the prevention of disease, owes an immense debt for his demonstration of the universal distribution of bacteria, of the value of accurate sterilization, and of the fallacy of supposed spontaneous generation; for the introduction of an accurate technique, and perhaps above all for the example and inspiration of a thoroughly scientific method in medical work and research. Just as he confuted the hypothesis of spontaneous generation of bacteria, so he dealt with the prevalent conception of spontaneous morbidity so obstinately supported by Liebig. In the contrast between the state of national health and the prospect of life in the civilized world now and that existing fifty years ago, the influence of Pasteur is writ large; and, as Professor F. Widal\* said in his *éloge* on December 26th, 1922, at the Académie de Médecine, no science has ever experienced such a revolution as that effected in medicine by Pasteur's discoveries. In conclusion, it is fitting to quote from the Supplement to *Nature* of December 23rd, 1922, Professor William Bulloch's considered judgement: "When one calmly surveys the immense progress of medical science in the last fifty years it will, we think, be admitted by future historians that its progress and success were largely due to the work initiated with so much imagination and carried out with such incomparable skill by Louis Pasteur."

#### THE MODE OF ACTION OF TRYPANOCIDES.

As will be gathered from a perusal of the report published this week (p. 149), the discussion at the Royal Society of Tropical Medicine upon the new trypanocidal remedies brought out a number of points of great practical and theoretical interest as to the mode of action of trypanocides. The facts reported by Dr. Low and Dr. Chesterman showed that each of the new remedies, "Bayer 205" and tryparsamide, is a real advance on any previous remedy for the treatment of trypanosomiasis. Dr. Low described 8 cases of sleeping sickness (*T. gambiense*) treated with "Bayer 205"; 7 recovered. Dr. Chesterman gave an account of the treatment (Stauleyville) of 40 cases of sleeping sickness with tryparsamide. He expressed himself as satisfied that the action of the drug was superior to that of atoxyl or antimony. A warning note was sounded by Dr. Derwish, who said that cures could often be obtained with antimony and salvarsan, and that the length of time during which the new drugs had been on trial was really insufficient to estimate their effects on a disease so notoriously liable to irregular remissions as was sleeping sickness. The experimental and clinical evidence seems to point clearly, however, to the conclusion that the two new drugs are stronger trypanocides than any previously known substances, and that a real advance has been made in the treatment of sleeping sickness. The interesting theoretical point arises as to the nature of their mode of action. Ehrlich's theory of chemotherapeutics was simple and picturesque, and received great support from the fact that work on the lines suggested by his theory led to the discovery of salvarsan. This theory, which was a development of the side-chain theory, was that a drug could be likened to an arrow—the shaft or toxic nucleus was the substance which killed the trypanosomes, whilst side-chains or haptophoric groups served the purpose of the barb in fixing the toxophoric group to the parasite. All recent developments in chemotherapy, however, have tended to discredit this theory and to suggest that the process is much more complex. If Ehrlich's theory is correct the action of trypanocides *in vitro* should be roughly parallel with their action *in vivo*. This does not happen; even in the case of salvarsan its action *in vitro* is much weaker than that of numerous other arsenic compounds which are valueless as

\* Widal, F., *Bull. Acad. de méd.*, Paris, 1922, 3<sup>e</sup> sér., lxxviii, 642.

trypanocides; tryparsanide, which is a pentavalent arsenic compound, has very little action on trypanosomes *in vitro*, while "Bayer 205" also has a relative feeble action under the same conditions. This difficulty can be got over by supposing that the drugs are slowly changed in the body into an active compound; but all available evidence is to the effect that drugs in general, and arsenic compounds in particular, are removed from the blood stream very rapidly, and that an hour or two after an intravenous injection only a small fraction of the drug remains in the blood stream. On the other hand, Voeghtlin and Smith's work showed that the trypanocidal action of salvarsan did not commence for two or three hours—that is, not until most of the arsenic had left the blood stream. Some of the recent work on trypanosomiasis points, indeed, to a totally different conclusion as to the mode of action of trypanocides. Marshall and Vassallo found that serum taken from salvarsanized patients and injected intrathecally had a powerful curative action. The quantity of arsenic in such serum must be almost negligible, and any action the serum exerts must be due to some trypanolytic substance produced by the body. Dr. Wenyon, as will be seen, stated during the discussion on the papers by Low and Chesterman that from experiments on mice he had concluded that the intravenous injection of "Bayer 205" in man caused the formation of a trypanolytic substance, both in the blood and in the cerebro-spinal fluid, and that this substance persisted in the circulation and was present a week after the injection. These observations are of the greatest importance, for they provide direct experimental support for the view that the action of chemotherapeutic agents is not necessarily a direct one on the parasites, but that it is, in part at any rate, an indirect action. At present the general view appears to be that the drugs kill a certain number of parasites, and that the destruction of these parasites causes the formation of trypanolytic substances, which carry on to completion the work of destruction. It is obvious that this new view of chemotherapy is much more complex than Ehrlich's original side-chain theory, and a large amount of experimental work will be necessary before any certain conclusions can be reached. The elimination of an incorrect theory is, however, in itself an advance, and the new orientation of ideas should prove a valuable stimulus to research along the new lines indicated.

#### SMALL-POX AND VACCINATION IN THE PHILIPPINES.

In this issue Dr. J. C. McNeil presents his examination and analysis of the reports on small-pox and vaccination in the Philippines. He states briefly his provisional conclusions, but urges that further inquiry is necessary, not by study of documents, but by actual visitation and investigation, perhaps by the Rockefeller Foundation, which has recently engaged in making a medical survey of the islands. It may, however, be permissible to state the general impression made by the facts at present available. The United States authorities on taking over the islands in 1898 were enthusiastic in their desire to eradicate small-pox, which had been so terrible a scourge under Spanish rule. To that end they decided on a vaccination campaign which was to include the whole population of the Philippines; but the difficulties in the way do not seem to have been fully appreciated. Neither the military nor civil health service could undertake the actual work of wholesale vaccination; for every detail they had to rely on Filipino or native agencies. The population to be vaccinated was ignorant, superstitious and apathetic, or actively hostile. A large proportion of the available assistants consisted of men who were not even in the lowest rank of the civil service of the islands. They included uneducated, lazy, untruthful agents, who wasted the lymph supplied to them and fabricated returns showing huge numbers of vaccinations which had never been performed. The natural difficulties also were immense—difficulties of distance and defective means of travel to remote insular groups of natives living under the worst conditions and understanding neither Spanish nor English; difficulties also

of climate and transport; whilst failure of ice supply for cold storage tended to cause deterioration of vaccine, and local incompetence or carelessness favoured further deterioration. Though such conditions may not have been universal, an important initial question seems to have been the suitability of the strain of lymph to the type of small-pox locally prevalent, and the Director of Health called attention in 1910 to the short duration of immunity which he had observed in Filipinos as compared with white-skinned races. Of the vaccinations alleged to have been performed a large proportion were never inspected, and in those inspected the percentages with negative results, even in infants, was extraordinarily high. These, briefly, were some of the conditions under which the United States authorities laboured in their efforts to protect the Philippines from small-pox. The exaggerated, if not fictitious, reports which they received of vaccinations by the thousand, or the ten thousand, or even the hundred thousand, not unnaturally misled them, and at the same time there set in a great irregular decline in the prevalence of small-pox. The 19,000 deaths in 1903 fell to 9,000 in 1904, to 4,000 in 1906, to 3,000 in 1910, to 1,000 in 1911, and to a few hundreds annually from 1912 to 1916. Then, apparently under the soothing influence of this diminution in small-pox, the dishonesty of vaccinators and their subservience to local influence led to increased neglect of duty, so that in the capital city, Manila, supplies of lymph were thrown away, whilst the usual returns of vaccinations continued to be made. The awakening came with the epidemic of 1918-20. The reports show that a great new scheme of vaccination was set on foot, and was being actively carried out in 1919 and 1920. Unfortunately, however, those engaged in the new campaign seem to have met with some of the difficulties, though not all, which belonged to the earlier crusades. In this statement of the position there may easily be mistakes and misunderstandings, or even unintentional injustice, and we submit it with all reserve. Whether the survey on behalf of the Rockefeller Foundation, which was in progress in May last year, is yet complete we do not know, but pending a report by it an open mind must be kept on the whole question. Finally, it may be well to point out, though it ought to be unnecessary, that the question of small-pox and vaccination in the Philippines has no bearing on the security of this country unless by some remote chance the black or haemorrhagic strain of infection were implanted here. Britain and the rest of Europe have times without number had ample proof that small-pox, as it occurs with us, and whether mild or severe in type, is absolutely controllable by vaccination and revaccination.

#### VITAL STATISTICS OF PRUSSIA BEFORE AND AFTER THE WAR.

THE Prussian Statistical Department issued last year the second part of Vol. 10 of *Medizinisch-statistische Nachrichten*. It is a comparative study of the last complete pre-war and the first complete post-war year (1913 and 1919). Prussia is closely comparable with England and Wales in population, and as it has been exposed to different wartime and post-war conditions, it is interesting to compare the results. The estimated population of Prussia in 1913 at all ages was 20,596,269 males and 21,052,793 females. In the first completed post-war year (1919) the census showed a decrease in the males to 18,816,849 and females to 20,523,598. The mean age of males in 1913 was 26.6 years, and 28.7 in 1919. There was very little change in infant mortality, the death rate per 1,000 births in the first month of life was 48.7 for 1913 and 48.3 for 1919. The births numbered 1,209,385 in 1913 and 827,335 in 1919, giving rates of 29.0 and 21.0 per 1,000 living. In England and Wales the birth rates were 23.9 per 1,000 living in 1913 and 18.5 in 1919, and the death rates in the first month of life were 44.39 and 44.49 per 1,000 births. In both countries there was an increase in the deaths in childhood, but the third wave of the great pandemic of influenza in 1919 may be assumed to account for some increase. In Prussia the decline in infantile diarrhoea was

considerable; the mortality under 1 year was 134.6 per 10,000 live births in 1913 and 44.55 in 1919. Excluding typhoid fever and influenza, the infectious diseases showed a decrease. The number of deaths from scarlet fever in 1919 was less than half that of 1913, being 2,213 against 4,506. In England and Wales 2,103 deaths were registered in 1913 and 1,221 in 1919. The deaths from measles showed a greater decline, from 7,235 to 1,270. The figures for England and Wales were 10,673 and 3,563. There was little change in the deaths from diphtheria and croup, the actual deaths being 7,550 and 7,054, and the rates of mortality at ages up to 15 were 5.42 in 1919 and 5.20 in 1913 (mortality per 10,000 living). The figures for England and Wales were 4,494 for 1913 and 4,916 for 1919, and the rates of mortality under 15 years 3.84 and 4.36 per 10,000. In Prussia the death rates from typhoid fever increased from 0.34 to 0.74 (actual deaths being 1,433 and 2,911). There was a decline in the figures for England and Wales from 1,505 to 577 (0.41 to 0.16 per 10,000). The greatest increase in the causes of deaths was under the head of tuberculosis. The totals were 56,861 in 1913 and 85,936 in 1919, and the crude rate per 10,000 increased from 13.65 to 21.86. The rates for urban districts increased from 15.81 to 27.16 and the rural from 11.65 to 16.84. In England and Wales the total deaths were 49,464 in 1913 and 46,310 in 1919. "The special characteristic of the mortality from tuberculosis in the years under consideration and that which gives rise to the greatest anxiety is the increase of mortality at young ages. Despite the end of the war, the partial improvement of feeding, clothing, and heating, normal facilities for medical treatment, and above all the declining birth rate, which would give reason to suppose that more and better attention under the more favourable external conditions of a smaller family would lead to a decline of the death rate, the number of deaths has not in fact declined but increased, a result which is doubtless to be attributed to the aftermath of the hunger blockade." The statistics of pneumonia and influenza show the effect of the great pandemic in 1919. The deaths from influenza were 1,592 in 1913 and 29,141 in 1919. In England and Wales the figures were 6,337 in 1913 and 44,789 in 1919, but the two sets of figures are not comparable owing to the differences in tabulation. The total mortality from influenza and pneumonia was 53,094 and 85,990 in 1913 and 1919, and the corresponding figures for England and Wales were 44,002 and 83,909. The cancer rate shows very little change, 10.13 in 1913 and 10.03 in 1919 for 10,000 persons at ages 30 to 60, and for persons over 60, 54.16 and 51.14. In 1920 the rate increased to 10.22 (ages 30 to 60) and 55.05 (60 and over), the latter being the highest yet recorded.

#### THE EXCRETION OF VITAMINS.

ONE of the first facts established about vitamins was that they could pass through the animal body unchanged; all the evidence indicates that animals cannot synthesize vitamins, but must obtain them in their foodstuffs, and yet vitamins are excreted in considerable quantities in milk provided the cow receives an adequate quantity of them in her food. Less attention has been paid to the excretion of vitamins in the urine and faeces, but in the current number of the *Biochemical Journal* there is an interesting article by Dr. Van der Walle dealing with this question. He recalls that several observers have demonstrated the presence of the water-soluble antineuritic vitamin in the urine. He confirms this conclusion, and shows that the urine of men or dogs contains a substance which has a strong curative action upon pigeons suffering from polyneuritis. This substance is shown to possess properties similar to those of vitamin B, for it is destroyed by heat, and is adsorbed by animal charcoal; moreover, it is absent from the urine of dogs fed on a diet free from vitamin B. Other experiments were made to ascertain whether the antiscorbutic vitamin occurs in the urine, but the results were negative. These experiments are of considerable interest, for they suggest that it may be possible to determine directly by examination of the urine whether any

particular case of disease is actually suffering from a deficiency of vitamins in the food. Experiments on these lines might lead to a rapid extension of our knowledge about the influence of vitamin lack upon the occurrence of disease.

#### HYGIENIC METHODS OF INDUSTRIAL PAINTING.

OF the operations involved in the practice of industrial painting, that of dry rubbing down is most productive of dust. The process consists of rubbing a painted surface with an abrasive in order to smooth the surface before the application of a new coat of paint. What is commonly called sandpaper is used for this purpose; it consists of flint, emery, powdered glass, or some such material, fixed to paper or other fabric by glue. Large quantities of dust are produced in the operation, and this settles on the floor or on the painter's overall, where, being white, it is not detected, so that it often happens that a man wears an overall for days, apparently in a clean condition, but really impregnated with loose lead dust, some of which, when disturbed by his movements, enters the air and is breathed. In a paper read before the Royal Society of Arts on January 17th Mr. C. A. Klein gave an account of his investigations, which showed that the older—and consequently the harder—the paint film, the greater is the amount of small dust, and it can be detected at a distance up to ten feet from the surface at which it is created. Mr. Klein urged that a grave danger of lead poisoning attended the use of the dry rubbing down process, which should therefore be prohibited. In view of the prevalence of respiratory diseases among workers exposed to siliceous dusts, he had analysed paint dusts and found particles of abrasive material—sand, glass, and the like—to be contained in quantity. The increased death rate from phthisis among painters was emphasized in evidence before the Departmental Committee on the use of paints containing lead in the painting of buildings, and a higher percentage of deaths due to phthisis among painters than among occupied males generally was also shown in figures from the Netherlands and from America. Apparently it was not the lead itself which was responsible, and Mr. Klein suggested that there was a case for inquiry. Crystalline silica was regarded as the principal vehicle of dust phthisis, and his own investigations went to prove that the sharp dusts of abrasives which occurred in paint dust as breathed by the painter contained free silica in a size of particle which might be regarded as dangerous to the lungs. A wet process of rubbing down has been known for many years, but for certain reasons appears to be regarded by the trade as unsuitable for general application. Lately, however, a damp rubbing down process has been evolved in which the painted surface is damped by means of a wetted sponge, and then rubbed with ordinary sandpaper, followed by the use of a clean wet sponge to remove the paint and abrasive material in a dustless condition. The "dust figure" in this process has been shown by experiment to be negligible, and in the opinion of expert painters the surfaces obtained are smoother than those obtained by the dry process. The National Federation of Master Painters of Great Britain has expressed its approval. In America a new waterproof abrasive paper was said to be a distinct improvement on ordinary sandpaper for this purpose. Dr. T. M. Legge, the Chief Medical Inspector of Factories, who presided over the meeting, thought the new procedure very welcome, although on the administrative side he was a little doubtful about the possibility of securing its general adoption, in view of the fact that the painting trade, like all others, is largely governed by tradition. With regard to the question of fibroid phthisis in the house painter, Dr. Legge deprecated anything in the nature of a "stunt," such as that which took place a couple of years ago in connexion with the same condition among printers. It was very tempting to investigate the conditions of the atmosphere, to work out certain not too convincing statistics, and on finding silica dust in the air to say, without reference to the persons concerned, or any study of their particular cases, that as a form of phthisis was due to silica dust the phthisis occurring in the craft must be

due to this cause. He doubted whether the quite definite condition of fibroid phthisis had been found in the lungs of house painters any more than in those of men of other trades. Sir Kenneth Goadby, who also took part in the discussion, said that he was in some measure responsible for the initial suggestion that the silica dust in sandpaper might be associated with phthisis, if in fact the phthisis reached a high incidence, but there was not sufficient statistical evidence that house painters showed so large an excess of phthisis of a type which could be attributed to dust of this nature.

#### VIBRATING SENSATION.

When the foot of a vibrating tuning-fork is placed over subcutaneous bony prominences or surfaces, in many parts of the body, a peculiar vibrating sensation is felt. To this sensation the names of "vibrating sensation or feeling," "bone sensibility," and "pallaesthesia" have been given. A clinical lecture by Dr. R. T. Williamson of Manchester on the value of the vibrating sensation in the diagnosis of diseases of the nervous system was published in our columns in 1907 (vol. ii, p. 125). It was pointed out there that the method was a delicate test for detecting slight impairment of sensation. Dr. Williamson has given an account of his further observations on the subject in a paper recently published in the *American Journal of Medical Sciences*.<sup>1</sup> He has continued to employ the method as a routine, using a large tuning-fork seven and a half inches long (A. 440) with an oval metal footpiece. He finds that suitable points for testing the sensation are the inner surface of the tibia, the malleoli, the anterior superior iliac spine, the nail of the big toe, the sternum, and the styloid process of the ulna. Normally the vibrating sensation is felt on the points mentioned. In many diseases the vibrating sensation is lost when other forms of sensation (for touch, pain, temperature) are retained; and it is often the first form of sensation to be lost. In many diseases it is never lost even up to the end of the affection. For this reason Dr. Williamson believes the vibrating sensation is often of value in differential diagnosis; sometimes it is of service in the localization of spinal lesions. In multiple peripheral neuritis from alcohol, and in diabetic neuritis, loss of the vibrating sensation can usually be detected before loss of any other form of sensation. In these cases four valuable early signs are pain in the legs, tenderness of the calf muscles, loss of the tendo Achillis jerks, and loss of the vibrating sensation. In the differential diagnosis between peripheral neuritis and anterior poliomyelitis (acute or chronic) the vibrating sensation is often of service, since it is never lost in anterior poliomyelitis, but is usually lost very early in peripheral multiple neuritis, though at first other forms of sensation may be felt. In the diagnosis between anterior poliomyelitis and acute disseminated myelitis or myelitis not limited to the anterior horns, the vibrating sensation is of service; if lost the disease is not limited to the anterior horns of grey matter. In an early stage of combined postero-lateral degeneration or sclerosis the chief indications may be loss of the vibrating sensation on the legs, slight inco-ordination in walking, or affection of the muscular sense in the legs, and an extensor type of plantar reflex. In disseminated sclerosis, if sensation should be affected, the most common early form of sensory impairment is loss of the vibrating sensation. It may be lost on the legs, or on the legs and abdomen, or on the abdomen only. The abdominal reflexes are often lost and the plantar reflexes are often of the extensor type at this early period. In compression myelitis from vertebral caries, or tumour in the spinal meninges, at the early stage, if sensation be affected, the vibrating sensation is usually lost before other forms of sensation, and the same is true of Erb's form of spinal syphilis. The vibrating sensation is occasionally of service in the diagnosis between functional or hysterical anaesthesia and anaesthesia due to organic disease (and between functional and organic hemianaesthesia). When the foot of a

vibrating tuning-fork is placed at one point over a bone the vibrations are felt, not only at that point, but (though with diminishing intensity) at all parts. If one part of a bone, such as the sternum or tibia, be in an area of anaesthesia and another part not, then, if the foot of the vibrating tuning-fork be placed on the bone in the anaesthetic area, the vibrations, if not felt there, should be felt at the distant part of the bone, in the non-anaesthetic region. If this should not be so, then the case is one of hysteria or malingering.

#### INTERNATIONAL AIR CONGRESS, 1923.

An International Air Congress will be held in London this year, from June 25th to 30th, at the invitation of the British Government, under the presidency of the Duke of York, who holds the rank of Group Captain in the Royal Air Force. Lord Weir is vice-president of the Congress, and the Duke of Sutherland, Under Secretary of State for Air, is chairman of the main committee. The chief object of the Congress is to provide opportunities for the reading and discussion of papers on every aspect of air matters; it will be divided into four groups, each again divided into subgroups, which will meet simultaneously. Group A will deal with methods of research, aerodynamics, and similar subjects; Group B with fuels and lubricants, etc.; Group C will discuss air transport and navigation problems, under the heading of (1) technical aspects, (2) engineering problems, (3) commercial, legal, and financial problems, and (4) medical aspects; Group D will devote itself to airship design and the military utilization of civil personnel in machines. The reading of papers will occupy the Monday, Wednesday, and Friday of the week, while Tuesday and Thursday will be devoted to visits to various places of interest. The Air Ministry have arranged for an air pageant on Saturday, June 30th. Further particulars and a form of application for membership of the Congress may be obtained from Lieut.-Colonel W. Lockwood Marsh, general secretary of the Congress, c/o the Royal Aeronautical Society, 7, Albemarle Street, London, W.1.

#### THE INTERNATIONAL PHYSIOLOGICAL CONGRESS.

It has already been announced that the eleventh International Physiological Congress will be held in Edinburgh next July (23rd to 28th), under the presidency of Sir Edward Sharpey Schafer. The first meeting of the Congress was held in 1889, and it met in Cambridge in 1898; since then it has not visited Great Britain. The Congress met in Groningen in 1913, and not again until 1920, when it assembled in Paris. A meeting of the General Committee of Organization has been held this week in Edinburgh, under the presidency of the Lord Provost, who expressed his appreciation of the honour done to the Scottish capital by its choice as the meeting-place of the Congress this year, and the compliment thus paid to the worldwide scientific reputation of the University of Edinburgh, and in particular of its medical school. The Lord Provost said that the corporation of the city would extend a hearty welcome to the illustrious visitors expected, and expressed the expectation that the citizens would readily offer private hospitality. On the motion of the Principal of the University (Sir Alfred Ewing), seconded by Sir George Berry, M.D., M.P., the appointment of Sir Edward Sharpey Schafer as president, made at the Congress in Paris, was confirmed, as were also the appointments of Professor A. R. Cushny, F.R.S., as treasurer, and of Professors O. Barger and J. C. Meakins as joint secretaries. An executive committee was appointed on the motion of Professor G. L. Gulland, seconded by Dr. J. L. Ewing, and committees for hospitality and for making scientific and social arrangements were also appointed. The meeting was brought to an end by a vote of thanks to the chairman, proposed by Sir Edward Sharpey Schafer, who expressed gratitude to Lord Provost Hutchison for his sympathetic interest in the Congress and his cordial promise of co-operation. We understand that inquiries may be addressed to the assistant secretary, Miss Dorothy Charlton, at the Department of Physiology, the University, Edinburgh.

<sup>1</sup> Vol. clix, No. 5, p. 715.

## MURDERS.

THE White Paper (Cmd. 1787 of 1922) recording the number of cases of supposed murder in England and Wales in 1912, 1913, 1920, and 1921 (excluding cases of infanticide of children under one year by mother and deaths from illegal operations) is an interesting example of the fact that a popular impression may be altogether false. We think that anybody would have expected *a priori*—we certainly did ourselves—that the habituation of so many thousands of men to deeds of violence, the tale of horrors which were our daily fare for so many years, would be reflected by a sensible increase in the frequency of violent crimes after the war. But, so far as cases of supposed murder are concerned, the expectation is falsified. In 1912 there were 93 supposed murders, in 1913 there were 100, in 1920 there were 107, and in 1921 only 85. In 1921 a somewhat smaller proportion of persons were convicted, either of murder or a lesser crime, in connexion with the cases than in the other years. Thus in 1912, 38 persons were convicted of murder, 25 of manslaughter, and 2 of feloniously wounding—65 convictions with respect to 93 cases; in 1921, 23 persons were convicted of murder, 14 of manslaughter, and one of maliciously wounding—38 convictions for 85 cases; but in each of these years 7 suspects were found to be insane; 16 murderers committed suicide in 1912, and 22 in 1921; so that 88 out of 93 in 1912, and 67 out of 85 in 1921, may be said to have been accounted for—percentages respectively of 90 and 79. The net result is that neither in frequency nor in immunity from detection does the post-war experience of murder differ very much from that of pre-war times.

## PASTEUR—THE ARTIST.

At the celebration of the hundredth anniversary of the birth of Pasteur, which is to take place at the Royal Society of Medicine on February 28th, the President, Sir William Hale-White, will give a short address, and Dr. Gustave Monod, of Paris and Vichy, will read a paper, illustrated by lantern slides, on "Pasteur—the artist." Pasteur early showed a taste for drawing; his inclination in this direction was in fact a source of some anxiety to his father. He began to attempt portraits in coloured chalks: one of the earliest, done when he was a boy of about 13, was of his mother; it is said to be not unlike the work of a conscientious pre-Raphaelite. The reproduction we have seen in black and white in *l'illustration* is spirited. It shows a middle-aged woman, with sharp, alert features, wearing an old-fashioned frilled cap and check shawl. When, after his short experience in 1838 of the Lycée St-Louis, in Paris, he returned to his home at Arbois, he made a number of pastel portraits of local celebrities and friends of his family. Among the portraits he did at this date was one of his father, a sedate contrast to his mother; it shows a middle-aged man, with features not unlike those of his great son, wearing the stock and thick roll coat-collar of the period. Within a year, however, Pasteur had gone to the college at Besançon; he worked hard and took the degree of Bachelier ès lettres in August, 1840; and his artistic ambitions seem never to have revived.

We have to announce with very great regret the death, on January 23rd, of Dr. J. W. Ballantyne of Edinburgh, after a short illness, which necessitated an operation from which he did not rally. We intend to publish a notice of his life and work in an early issue.

THE Milroy lectures on canned foods in relation to health will be given before the Royal College of Physicians of London by Dr. W. G. Savage, on February 22nd and 27th and March 1st; Dr. Geoffrey Evans will deliver the Goniatonian lectures on March 6th, 8th, and 13th, on the nature of arterio-sclerosis; and Dr. Arthur J. Hall will give the Lumleian lectures on encephalitis lethargica (epidemic encephalitis) on March 15th, 20th, and 22nd. The lectures will be delivered at the College, Pall Mall East, S.W., at 5 p.m. on each day.

## England and Wales.

## THE HASLEMERE AND DISTRICT HOSPITAL.

The new hospital of thirty-five beds, for Haslemere and district, which has been built at a cost of £32,000, was formally opened on Saturday, January 20th, by the Lord Chancellor, Viscount Cave, in the presence of a large company. The hospital needs of the neighbourhood have hitherto been served by the Hindhead and District Cottage Hospital, with twelve beds, which was founded in 1897. In declaring the new hospital open, Lord Cave remarked on the wisdom of those who still favoured the maintenance of the voluntary hospital system. He disagreed altogether with the short-sighted view that all hospitals ought to be State institutions. He was well aware that the Poor Law infirmaries did much good work, but the fact remained that they could not deal with out-patients. Moreover, it was impossible to get in State institutions the same constant, thoughtful, daily care which was given by doctors and nurses alike in the voluntary hospitals of this country. The committee of inquiry of which he was chairman received evidence from countries in which the hospitals were entirely State institutions. It appeared from this that in such hospitals there was no one, apart from the patient's relatives, whose duty and pleasure it was to see him from day to day, to watch over his comfort, and give him that personal attention which meant so much to a sick person. Moreover, the voluntary hospitals in this country had the enormous advantage of being worked by the medical profession. He thought it was not generally realized to the full how much the public owed to doctors for the great voluntary work they gave to these institutions.

## THE NEW SPIRIT IN PSYCHIATRY.

The annual report of the Derby Borough Mental Hospital for 1921 reproduces the report of the Commissioners of the Board of Control on their visit of inspection to that institution towards the close of the year. The following observation of the Commissioners seems of general interest and worthy of quotation as a sign of the modern attitude towards the scope and purpose of a mental hospital:

"We are glad to hear that the committee's resolution to appoint a visiting dental surgeon, which was passed in 1914, but delayed in operation by the war, is likely to mature shortly; and we hope it may lead up to the appointment of other visiting specialists. We saw, for instance, among the thirty-six patients whom we found in bed, several cases for whom expert surgical opinion would be of value. The proximity of the institution to the well known general hospital in the town leads us to express the further hope that it may some time be found possible to institute out-patient work in mental disorders at the latter, and that for this purpose the experience of the medical staff here could with advantage be made available."

## Scotland.

## SCOTTISH POOR LAW MEDICAL OFFICERS' ASSOCIATION.

The annual report of the Scottish Poor Law Medical Officers' Association recalls that the Scottish Committee of the British Medical Association interviewed the Scottish Board of Health in regard to the question of tenure of office, but failed to move the Board. Attempts have been made to rectify the anomalous position of Scottish Poor Law medical officers for many years past, but so far without result. It is manifestly unfair that English Poor Law medical officers should have an appeal against injustice, and also that medical officers in the crofting counties in Scotland should have what amounts to similar protection, while medical officers in the rest of Scotland hold their appointments at the absolute caprice of the parish councils. The intention of the Association is now to approach the Council of the British Medical Association and to endeavour to obtain its assistance in approaching Parliament by a private bill. Some correspondence took place during the year in regard to Poor Law medical officers supplying drugs out of their salaries. The advice was given that the Scottish Board of Health did not approve of drugs being included in the salary of the Poor Law medical officer, and that to supply drugs out of the Poor Law medical officer's salary was illegal, except in cases where it was specifically mentioned in the agreement.

In no case during the year was it found necessary to take any action in regard to vacant appointments. A recent Act authorizes the granting of superannuation to all local government officials, including medical officers; it is contributory, but voluntary on the part of parish councils, and the report raises the question whether many parish councils will be likely to adopt the Act.

#### QUEEN VICTORIA JUBILEE INSTITUTE.

The Lord Provost of Edinburgh presided over the annual meeting, on January 16th, of the Scottish Branch of the Queen Victoria Jubilee Institute for Nurses. In regard to the financial position of the Institute, the Lord Provost said that it was a matter of grave anxiety for the council to report that there was a deficit of £6,125 on the ordinary revenue account for the past year. That had been met to a certain extent by a number of legacies and the proceeds of special appeals, leaving a net deficit of £1,213, and after the accounts were made up a grant of £2,000 was received from the Scottish Branch of the Red Cross Society. It was evident, however, that the regular occurrence of such windfalls could not reasonably be expected, and the state of the finances represented a serious position. Professor T. H. Bryce (Glasgow) emphasized the very extensive ramification of the work of the Institute throughout Scotland. They had now 341 affiliated nursing associations, of which 28 had been added during the past year. The Board of Health recognized that in the organization provided by the Institute there was a suitable basis for building up that national domiciliary nursing service at which it aimed. Sir Norman Walker said that domiciliary nursing properly carried out could prevent a great deal of disease, and that was one of the most important points of nursing work. They wanted to arouse a healthy conscience in every section of the community. Dr. Walter Elliot, M.P., the new Under Secretary for Health for Scotland, spoke of the importance of domiciliary nursing, for it was often the turning point between sending a patient to an overburdened hospital or keeping him at home. He was especially interested to find that the Institute had been able to work with the Scottish Board of Health. The essence of the preventive side of disease was voluntaryism and not compulsion. They could not carry out preventive work without the co-operation of the people in the home.

#### ROYAL GLASGOW ASYLUM FOR THE BLIND.

At the annual general meeting of the Royal Glasgow Asylum for the Blind, held on January 15th, Mr. Joseph Waugh, chairman of the managers, said that during the past two years they had had many meetings with the representatives of local authorities, the Scottish Board of Health, and others with a view to adjusting the conditions under which the duties hitherto performed by the managers would fall to be carried out by those who succeeded them in office. A Parliamentary bill had already been framed, and it was assumed that it would become law without opposition. This bill provided that the asylum would be handed over in its present complete and active state, that they should be relieved of every obligation, and that the whole future charges would fall on the public funds. They were interested in seeing that the work should be carried out efficiently, and they might rest assured that it would not be prejudiced by the proposed change of ownership and responsibility. Deaf and dumb institutions, associations to help the physically and mentally defective, and asylums for the blind were all means of educating the public mind in its duty and responsibility, and with society in a state of development it was inevitable that the time should come when it would not be possible by voluntary means to provide the money required for such vibrations. In agreeing to the transfer of the Royal Asylum it legs and abdomen, and because that was not true; they handed over reflexes are often a building or equipment in a high state of the extensor type at myelitis from vertebral meninges, at the early stage vibrating sensation is usually sensation, and the so.

syphilis. The vibrating in the diagnosis between fun- within the last year or so circulars and anaesthesia due to organ. Dublin asking the recipients to tional and organic hemianaesthesia; after paying for certain some charitable object. The weepstake, the object to be

benefited being a cancer fund. The subject was a matter of discussion recently in the Irish Free State Parliament. It was raised by a Labour member, who asked the Minister for Home Affairs to state what his intentions were with regard to exceptions under the Lottery Act, and to outline the policy of the Government, as there were people who believed that Ireland was a second Monte Carlo. In reply, Mr. Kevin O'Higgins said that early last year the Provisional Government had in several instances given undertakings not to enforce the law. The matter had been carefully considered with the view of ascertaining whether it would be possible to make exceptions in favour of sweepstakes for charitable purposes; he had come to the conclusion that there was no middle course, and about a month ago it was decided that no undertaking should in future be given not to enforce the existing law. Charitable institutions would have to find other means of support. The sweep evil, Mr. O'Higgins continued, was spreading. Things had got long past the stage of sweeps being run for charitable institutions. People went to an institution deserving of charity and said, "You could do with £5,000, and we could do with £10,000. Could we use your name for a sweep?" Mr. Gorey congratulated the Minister on making "a clean sweep of the sweep."

### TURPENTINE OR LEAD POISONING A CAUSE OF PUNCTATE BASOPHILIA.

SIR,—In the BRITISH MEDICAL JOURNAL (January 20th, p. 103), in an article on "The blood as guide to early diagnosis in lead poisoning," Dr. Robert Craik makes the statement:

"It is safe to say that, in the absence of serious anaemia, punctate basophilia is more likely to be caused by lead than by anything else."

It is not generally known, even by experts, that inhalation of turpentine vapour can also cause basophilia indistinguishable from that produced by lead. The only reference I have seen to this is in a Blue Book on lead poisoning by paint (Cd. 7882, 1921, p. 60), wherein Sir K. Goadby found in experiments on animals that "basophilia staining was found with both turpentine and white lead, and even the animals exposed to zinc oxide and zinc sulphide showed the presence of a few basophils in the blood."

Since painters are the most likely people to suffer from lead poisoning, and since in their work the effects of lead and turpentine (or its substitutes) cannot be disentangled, it is important to realize that basophilia may be produced by turpentine as well as lead, especially in legal cases.

Can basophilia also be produced by turpentine substitutes—for example, white spirit—which are cheaper and widely employed? I fancy this point has not been determined. But I investigated a year ago the comparative toxic effects of turpentine and white spirit (and paints) on vegetable plasm (moulds and bacteria). I concluded that the had slight toxic effects. Also from the available I thought that men working in these vapours were them at first, but soon became accustomed which their health was not appreciably affected produced by large or summated doses of the seemed to be similar on the kidneys, the the nervous system. In the two latter be a fat-solvent effect. But I have studying the effects on the health in varnish alone. Here the prob- by the effects of lead. If any paring the effects of turpen varnish workers I should be or publish the results.—I am,

Hull, Jan. 22nd.

Senior Pl.

### EFFECT OF ANAESTHETICS.

SIR,—The communication by Dr. (January 13th, p. 61) raises questions of inasmuch as there is a tendency to adv anaesthesia, particularly for operations on the I believe it is claimed that the resulting tranq patient offers advantages to the operator withou the anaesthetic risk. But the light ether anaesthesia in Bristol for many years past, as far as my experience.

affords all the tranquillity to be desired for the majority of cases, and appears to lessen the risks of post-operative pulmonary complications, and this, if true, is a matter of great moment.

Dr. McDowall states that the abolition of the bronchiole function must necessarily throw a greater strain on the alveoli and cause them to be exposed to particles which otherwise would not reach them. It seems to me that localized bronchiolar paralysis, so far from throwing a strain on the corresponding alveoli, results in their collapse, and the only particles that would reach them in consequence would be organisms which spread down from the paralysed bronchiole, no longer capable of contractions, expelling abnormal secretions. In 1903 I published an article "On the rhythmical contractions of the bronchiolar muscular coat as a factor in pulmonary disease,"<sup>1</sup> and I suggest the effect of anæsthetic bronchiolar paralysis is analogous to a similar condition induced by acute inflammatory myositis. The far-reaching import of rhythmical bronchiolar contraction in pulmonary pathology is perhaps somewhat underestimated.—I am, etc.,

Clifton, Bristol, Jan. 15th.

P. WATSON-WILLIAMS, M.D.

#### APITUITARISM AND THE ANENCEPHALIC SYNDROME.

Sir,—Dr. F. J. Browne's letter in your issue of January 13th has made quite clear that in his original article he included both hypopituitarism and apituitarism in his theory of the etiology of the anencephalic syndrome.

It is possible that Dr. Barlow's reference to "hypoplasia of the thymus" is a verbal error, for I believe it is generally recognized by those who have experience in ante-natal pathology that in the anencephalic foetus the thymus is more often enlarged than not. In eleven non-macerated specimens I found the ratio of thymus weight to body weight to be as 1 to 100, 131, 133, 145, 149, 158, 162, 170, 207, 230, and 318 respectively.

I regret that I did not make a microscopical examination of the tissue occupying the pituitary region. It is well, however, to remember that the histological appearance of a tissue is not always an indication of its functional activity; the pituitary cells found in Dr. Barlow's specimens may have been physiologically abnormal.

In the examination of my specimens I found all the characteristic abnormalities which have been grouped together as the anencephalic syndrome. Furthermore, I have noted that the percentage of other developmental errors, such as kidney deformities, in cases of anencephaly is higher than in non-anencephalic foetuses. I have also been able to confirm the observation of P. S. Abraham (1883) that the musculus sternalis is frequently present.

All will agree that the gross irregularities found in anencephaly are very generalized in distribution. In the ductless gland system alone three at least (pituitary, thymus, and suprarenals) are frequently abnormal, and I do not think that we yet possess sufficient evidence to prove that the pituitary gland is the ringleader.—I am, etc.,

Liverpool, Jan. 15th.

NORMAN B. CAPON.

#### ADDER BITE.

Sir,—The interesting account of viper bite by Dr. Bernard, and translated by Dr. A. S. Gubb of Algiers (January 6th, p. 41), recalls a personal experience some years ago at Platæa on the Grecian coast.

One night a brother officer was brought to me suffering from a recently inflicted bite of the left index finger by a two-headed viper, which a day or two before he had found ashore on the rocky soil, and had in the interim kept in a cigar box. At night in question, in attempting with his left index finger to feel the snake in its somnolent (hibernation) state, it suddenly bit and inflicted the injury as stated above. Two distinct wounds were to be seen on the pulp of the left index with but little bleeding or pain. I immediately placed the finger around the wrist and freely excised the area of the bites, applying potassium permanganate in powder. The patient was placed in bed, with frequent and regular doses of alcohol.

In the course of the next three days the left arm became extensively swollen and of a bluish tint, together with involvement of the scapular gland above the elbow and all the axillary glands. Temperature 101° F. From the fourth day the conditions noted gradually subsided, the alcohol being replaced by a diffusible stimulant mixture, and in less than three weeks both local and constitutional conditions were entirely recovered from.

<sup>1</sup> Bristol Medico-Chirurgical Journal, March, 1903, p. 1.

The snake was about two feet in length, of a greyish body with black patches, and two well marked horns surmounting its head.—I am, etc.,

W. EAMES,

Bournemouth, Jan. 14th.

Surgeon Rear-Admiral R.N. (retd.).

#### NYSTAGMUS.

Sir,—Is nystagmus occurring in miners an entity by itself, or is it the same as nystagmus occurring in people who are not miners? Dr. Lister Llewellyn says they resemble each other. It has always seemed to me that they are identical, even in their etiology. Common to all cases of nystagmus is imperfection or absence of retinal images. Exceptions to this rule are cases of labyrinthine origin, cases that are hereditary, and cases occurring as terminal manifestations of a general disease—that is, cases that are not peripheral but central in origin.

In your issue of January 6th you take notice of Mr. A. S. Percival's paper, "A neglected factor in the etiology of miners' nystagmus." Mr. Percival wrote: "I submit that, say, 5 per cent. of all children born have a predisposition to the disease, and if they have not this predisposition they will never acquire it." This submission, I presume, applies to nystagmus occurring in children.

During the last two years I have seen twelve children suffering from nystagmus. Eleven of these children had decided degrees of ametropia; five of them had hypermetropic astigmatism, two mixed astigmatism, and four myopia of 6 D. and upwards. (Other observers may be able to confirm or dispute this association.) Had the ametropia and the consequent defective vision from imperfect retinal images nothing to do with the production of the nystagmus in these cases? From observations made in Glasgow I found that only 10 per cent. of all cases of nystagmus were miners, and now I ask the question: Is the term "miners' nystagmus" not a misnomer?—I am, etc.,

Cambuslang, Glasgow, Jan. 26th.

J. A. WILSON.

#### VITAMIN CONTENT OF CERTAIN PROPRIETARY PREPARATIONS.

Sir,—The managing director of Messrs. Virol (Mr. A. E. Caune) complained, in a letter published in your last issue, that our article on the vitamin content of certain proprietary preparations was "apt to produce a misleading impression in the minds of medical men." We fail to see that he has proved this charge. Our aim, as he recognized, was to determine whether the proprietary preparations examined contained vitamins in a concentrated form. We found that they did not, but Mr. Caune has stated that "as regards Virol nothing of the sort has been attempted, and no such claim has ever been made."

We made no reference to any property of Virol other than its vitamin content, and therefore any discussion of its other virtues is beside the point. We cannot see that we have misled the medical profession in any way.—We are, etc.,

University College, London,  
Jan. 22nd.

KATHARINE H. COWARD.  
A. J. CLARK.

#### DANGEROUS DRUGS REGULATIONS.

Sir,—It is to be hoped that the paragraph on page 8 of the Times of January 13th will not escape the attention of the medical profession. It is headed "Dangerous Drugs Act—Right of Entry to Doctors' Houses," and sets forth the "means of inspection" approved by the Home Office, as follows:

"This, in the case of doctors and dentists, is to be carried out by medical officers of health, who will have the right of entry to premises without giving previous warning."

Surely no such insult has ever been offered to the profession as a whole. The thing is hardly credible, yet when one turns to the Memorandum on the Dangerous Drugs Act published in the BRITISH MEDICAL JOURNAL of the same date one finds the position to be as stated in the Times (see paras. 33-35 re inspection).

Is the profession to which one has devoted one's life fallen so low that one's stock of opium pills must be counted, one's tinctures and solutions sampled for analysis, and the ingredients of one's prescriptions disclosed at the demand of the medical officer of health (possibly a rival practitioner), entering one's private house in one's (probable) absence, and "without previous warning"? It is already ordained, while

we politically and journalistically are asleep. To this depth has the legislating mania of cranks and faddists reduced the once noble profession of the healing art, for the supposed benefit of a clique of degenerate addicts in the capital of the country, whose notoriety has aroused the maudlin sympathies of the newspaper-reading public.

Having no desire to be the first victim of the New Inquisition, I beg to subscribe myself by a *nom de plume*, but I will gladly volunteer to form one of the raiding party when inspection has to be made (without giving previous warning) of the house of the medical officer of health.—I am, etc.,

January 15th.

PRACTITIONER.

Since it affects part of our correspondent's argument we should point out that the *Times* was in error in stating that the inspection of registers and records will in future be carried out by medical officers of health. By reference to the full text of the memorandum published in our columns of January 13th (p. 69) it will be seen that paragraph 1 states "that it has been arranged that as a general rule this work shall be carried out in England and Wales by medical officers of the Ministry of Health, and in Scotland by medical officers of the Scottish Board of Health." Paragraph 31 states that the Home Secretary has authorized these officers, and apparently no other persons, to act as inspectors. We are informed that hitherto such inspection, at least in some districts, has been entrusted to police officers! We may add that the Council of the British Medical Association at its last meeting instructed the Medico-Political Committee to inquire into the working of the Dangerous Drugs Act so far as it affects medical practice.

#### CADET ORGANIZATION AND PREVENTIVE MEDICINE.

Sir,—In the daily round and common task it falls to my lot to observe scholars and adolescents from the anthropometric viewpoint. One fact stands out clearly—the evil influence exerted by the great war on the stamina of the 1905-8 age groups (1,600,000 lads). Rickets defect prevails in many children of the later groups. Overcrowding, faulty nutrition, absence of parental control, and State neglect have played their parts in this deplorable business.

Surely the time has arrived for the introduction of a universal cadet system, so that these 1905-8 age groups may benefit by discipline, games, and ten days' annual holiday camp. In the mother country Lord Haig's training area organization, at present in skeleton form, will serve us well, if made incarnate by these lads. The Australasian cadet costume, modified to suit our climate, affords an object lesson in cheap and hygienic clothing. For instructional staff, there already exists ample talent in this country.

Preventive medicine will never come into its own until we attain to a carefully planned routine for the guidance and kindly control of all our youths. The scrapping of the continuation schools renders an all-embracing cadet system imperative and urgent. No new Ministries are needed—the machinery is to hand. It rests with the members of our profession to insist upon its being set working, for we possess the confidence and affection of the nation in our exacting and dangerous calling, and our warnings will be heeded.—I am, etc.,

R. J. E. HANSON,

Surgeon Captain R.N.V.R.; Honorary Secretary  
of the Imperial Cadet Association,  
A.M.O. (Schools).

71, Pall Mall, London, S.W. 1, Jan 22nd.

#### Obituary.

HORATIO PERCY SYMONDS, F.R.C.S. EDIN.,  
Late Surgeon, Radcliffe Infirmary, Oxford.

We regret to record the death on January 16th of Mr. H. P. Symonds, formerly surgeon to the Radcliffe Infirmary, Oxford. He was born in 1851, the son of Mr. Frederick Symonds, a well-known surgeon in Oxford in his day. Horatio, who was the seventh of his line in uninterrupted descent to belong to the medical profession, was sent to Rugby under Temple, and from there went to study medicine at University College, London. In his student days he went out as a dresser to a field ambulance in the Franco-Prussian war in 1870. He took the diploma of M.R.C.S. Eng. in 1874, and held the post of house-surgeon to University College Hospital.

In 1878 he was appointed surgeon to the Radcliffe Infirmary, and in the same year he took the diploma of F.R.C.S. Edin.

He remained surgeon to the Radcliffe Infirmary for thirty-seven years, and was surgeon, and afterwards consulting surgeon, to Faringdon and Abingdon Cottage Hospitals, and to the Warneford Asylum, Oxford. He was also lecturer on surgery in the University. At University College Hospital he numbered among his friends Marcus Beck, and from him and Sir Rickman Godlee he was led to appreciate the value of Lister's teachings, which he at once applied when he entered upon independent practice. He kept himself acquainted with current surgical literature, and was always ready to put into practice new methods and ideas which commended themselves to his judgement. Not only was he a bold and speedy operator, but his surgical opinion was highly valued by his colleagues. Many of his house-surgeons will remember with gratitude the kindly help and encouragement they received from him and the opportunities he gave them of acquiring a practical knowledge of surgery. We are indebted to Dr. W. J. Turrell for the following:

"As house-surgeon of the Radcliffe Infirmary for two years during the early nineties, I was afforded an exceptional opportunity of forming an opinion of the value of Mr. H. P. Symonds's services to the hospital during a period when he was at the zenith of his powers as a surgeon. The chief impression left on my mind is the whole-hearted manner in which he devoted his life to surgical progress at a time when the recent introduction of antiseptics had so widely increased the scope and range of operative surgery. It was his quick appreciation of the possibilities opened up by the new methods and his careful attention to their most minute detail that gained for him his success as a surgeon, and enabled him to place and maintain the Infirmary in a leading and foremost position among provincial hospitals. His most striking characteristics were his punctuality, the rapidity with which he formed his decisions, the quickness with which he put them into action, and the precision with which he carried them out. His decisions, so rapidly formed, were strengthened by opposition and confirmed by contradiction, but were readily modified by tactful suggestion. He was always ready to try any new operation, instrument, or surgical method, adopting those which proved of benefit or utility, and quickly discarding those which failed to yield good results; in this way he instilled through the hospital a spirit of keenness and enthusiasm. As a teacher his example was invaluable; he was the kindest and most generous of friends, always appreciative of the work of others. The writer of this brief note is one among the many who will ever have cause to hold him in the most grateful and affectionate remembrance."

He was for many years an energetic member of the Committee of Management of the Radcliffe Infirmary; he attended regularly the meetings of the Oxford Medical Society and of the Oxford Division of the British Medical Association; in 1904, when the Association met at Oxford, he was president of the Surgical Section. He was surgeon to the Queen's Own Oxfordshire Hussars, and when the Territorial Force was formed became surgeon to the 3rd Southdown Hospital, with the rank of lieutenant-colonel. Soon after the war broke out, however, he was compelled greatly to curtail his activities owing to arthritis of the hip; the condition made rapid progress, and before long he was unable to walk—a great privation to him, as he had always been a man of very active habits. "All through his life," a writer in the *Times* (we understand Sir Herbert Warren) has said, "he had been a friend of the athletes. He had helped to train and advise many an Oxford eight, and year after year was to be seen stepping on the Oxford steamer at Putney to follow the race."

Mr. Symonds married in 1893 Miss Lecky, and leaves his widow and a son, Captain R. F. Symonds, who served in the war in the Oxfordshire and Buckinghamshire Light Infantry, to mourn his loss. The funeral took place on January 19th at Holywell cemetery, after a service at St. Giles's Church, which was very largely attended.

#### The Services.

##### FOREIGN DECORATIONS.

THE King has granted permission for the following recipients to wear the decorations conferred upon them in recognition of valuable services rendered during the war.

By the King of the Belgians.—Order of Leopold II. Cross of Commander: Dr. Alexander Granville, President of the Sanitary Maritime, and Quarantine Council of Egypt. Order of the Crown, Cross of Chevalier: Dr. Joseph M. Coplans.  
By the King of the Serbs, Croats, and Slovenes.—Order of St. Sava, Insigula of the Fifth Class: Mrs. Sophia B. J. Smith, M.D.

## VITAL STATISTICS FOR ENGLAND AND WALES, 1922.

We are indebted to the Registrar-General for the following statement regarding the birth rates and death rates and the rates of infantile mortality in England and Wales and certain parts of the country during 1922.

### ENGLAND AND WALES.

Birth Rate, Death Rate, and Infant Mortality during the Year 1922 (Provisional Figures).

	Birth Rate per 1,000 Total Population.	Death Rate per 1,000 Population (Crude Rate).	Deaths under One Year per 1,000 Births.
England and Wales ... ..	20.6	12.9	77
105 county boroughs and great towns, including London	21.5	13.0	81
155 smaller towns (estimated populations from 20,000 to 50,000 in 1921)	20.5	11.7	75
London ... ..	21.4	13.4	73

The death rate for England and Wales relates to the whole population, but that for London and the groups of towns to the civilian population only.

The birth rate of England and Wales as a whole is the lowest recorded except during the war years 1915-19, while the infant mortality is the lowest on record.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

THE electors to the Whitley Professorship of Biochemistry have appointed Dr. R. A. Peters to this chair. Dr. Peters is Fellow and Lecturer of Gouville and Caius College, Cambridge, and since 1919 has been Senior Demonstrator of Biochemistry in the University of Cambridge. He graduated in medicine in 1915 and proceeded M.D. in 1919. During the war he served with a commission in the R.A.M.C. (S.R.), being promoted brevet-major and winning the Military Cross.

### UNIVERSITY OF CAMBRIDGE.

CONGREGATIONS will be held during the Lent Term at 2 p.m. on February 10th and 16th and March 3rd and 9th.

A special syndicate to consider and report on the duties and responsibilities of the State Medicine Syndicate was appointed at a congregation held on January 20th. The members are: the Vice-Chancellor (the Rev. Dr. Pearce); Sir Hugh Anderson, M.D., Master of Gonville and Caius College; Dean, Professor of Pathology; Mr. William I. ... Professor of Civil Law; Sir F. J. M. Stratton, ... Mr. F. J. Dykes; and Mr. E. St. G. S. Goodwin and A. E. Clark-Kennedy have been approved for the degree of M.D.

The ... for the W. P. Surveyor.

The following medical degrees were conferred on January 20th:

M.D.—E. Beaton.  
M.B., B.Ch.—W. L. Berry.  
M.B.—S. P. Castell.  
B.Sc.—P. Verdon, H. A. A. Pargeter.

### VICTORIA UNIVERSITY OF MANCHESTER.

MISS MURIEL M. NUTT (Nat. Sci. Tripos Camb.) has been appointed Demonstrator in Bacteriology.

### UNIVERSITY OF EDINBURGH.

THE following have been appointed:—  
Materia Medica: Professor W. E. L. ...  
Midwifery: Professor Emeritus Henry Briggs (Liverpool).  
Professor Cossar Ewart has been reappointed a representative of Edinburgh University on the Council of the Scottish Marine Biological Association for the current year.

### UNIVERSITY OF ST. ANDREWS.

AT a graduation ceremony held on ... 19th Professor James Irvine presided. Stanley Allen, formerly of Edinburgh history. The following degrees were conferred:

M.P., Ch.B.—D. A. K. Cassells, Jean M. Davidson, W. S. D. Elder, M. A. B.Sc., Ruby N. Fergie, P. G. Grant, C. R. Henderson, Mary M. Jack, Norah M. Laidlaw, Grace B. McRae, Jean H. Merton, Janet L. A. Muirhead, M.A., S. S. Oslvie, A. B. Richardson, Nora A. M.D. Rodger, Jamiat Singh, Blanche D. S. Spence, W. A. Steel, W. Thomson, T. Wilson.  
M.D.—James Irvine.

### UNIVERSITY OF LONDON.

A COURSE of eight lectures on the physiology of the cortex as investigated by the method of conditioned reflexes will be given by Dr. G. Anrep, at University College, Gower Street, W.C.1, at 5 p.m. on Fridays, January 26th, February 2nd, 9th, 16th, 23rd, and March 2nd, 9th, and 16th. Attendance at this course is recognized in connexion with the B.Sc. (Honours) Degree in physiology. Admission to the lectures is free.

## Medical News.

AT the annual dinner of the Honourable Society of Cymmrodorion on January 19th, at which the Prince of Wales was the guest of the evening, he was presented with the medal of the Society and consented to become its patron. It was announced during the evening that Mr. Dan Radcliffe, shipowner, of Cardiff, had undertaken to present £50,000 in 3½ per cents., to the University of Wales in honour of the Prince, who is its chancellor.

THE next meeting of the Hunterian Society of London will be held at the Mansion House on Monday, January 29th, at 8.45 p.m., when the second Hunterian lecture will be given by Sir Berkeley Moynihan on the present position and treatment of gastric and duodenal ulcers. Discussion will follow.

THE festival dinner of the Royal Medical Benevolent Fund Guild will be held on Tuesday, January 30th, at the Hyde Park Hotel, London, with Lady Barrett, C.B.E., M.D., M.S., in the chair.

DR. MAJOR GREENWOOD, Reader in Medical Statistics in the University of London, will give a course of twelve lectures in the Department of Applied Statistics at University College, Gower Street, W.C., on the application of biometric methods to the study of nutrition, including history, theory, and experiment, on Mondays, at 5 p.m., beginning on February 5th. Miss Elderton, Galton Research Fellow, will also give an elementary course of twelve lectures on statistical methods on Thursdays, at 5 p.m., beginning on February 8th. The fees for the courses are one guinea each.

THE Maudsley Hospital of the London County Council will be opened formally on Wednesday, January 31st, by Sir Arthur Griffith-Boscawen, Minister of Health.

THE fifth annual reunion dinner for overseas medical officers, West Lancashire area, will be held on Thursday, February 8th, at 7.30 p.m., at the Exchange Station Hotel, Liverpool. Tickets may be obtained from the honorary secretary, Dr. J. W. Burns, 49, Rodney Street, Liverpool.

A SERIES of lectures in midwifery subjects will be given at Queen Charlotte's Hospital, Marylebone Road, N.W., by the members of the hospital staff at 5 p.m. every Thursday from February 1st to March 8th inclusive. These lectures are intended for students and practitioners, and are free.

THE King has granted to Dr. Leonard Bousfield, chief sanitary officer, Sudan Government, and Dr. Vincent S. Hodson, director, Civil General Hospital, Khartoum, his permission to wear the decoration of the Order of the Nile (third class) conferred upon them by the King of Egypt in recognition of valuable services rendered.

SIR NORMAN MOORE, Bt., M.D., who died on November 30th, 1922, left estate valued at £18,785.

THE Fellowship of Medicine has arranged a further series of post-graduate lectures, open to members of the profession, to be given, by the kind permission of the Royal Society of Medicine, at 1, Wimpole Street, during February and March. The opening lecture on Wednesday, February 7th, at 8.30, will be given by Mr. J. P. Lockhart-Mummery on diverticulitis, and others will follow by Dr. G. A. Sutherland, Mr. Cecil Rowntree, Dr. George Riddoch, and Mr. A. J. Walton. A course of six lecture-demonstrations on certain diseases of children will be held during February at the Children's Clinic, Western General Dispensary, Cosway Street, N.W.1, on Tuesdays and Fridays, at 5 p.m. The first will be given on Tuesday, February 13th, by Sir William Bayliss on "The physiology of digestion," and others on related subjects by Dr. Bernard Myers will follow, the concluding lecture on Friday, March 2nd, being devoted to "The nervous child, as seen in general practice." The fee for the course is one guinea; full particulars of both courses can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

IN honour of St. Apollonia, who, we are informed, was recently "installed as the Patron Saint of Dentistry," the organization called the Ivory Cross has arranged to hold a banquet at the Hotel Victoria, London, on February 9th. Tickets (price one guinea) can be obtained on application to any member of the Dental Committee, or at the offices of the Ivory Cross, 10, Henrietta Street, London, W.1.

Dr. J. M. H. MacFieon has been appointed consultant physician for diseases of the skin to the Metropolitan Asylums Board in succession to the late Sir James Galloway.

Dr. J. A. Ewan, on the occasion of his retirement from the office of medical superintendent of the Kesteven Asylum after twenty-six years' service, has received a public presentation.

An extraordinary general meeting of the London County Westminster and Parr's Bank, Ltd., will be held on February 1st, when it will be proposed to change the name to "Westminster Bank Limited." The proposal will have to be confirmed at another meeting, to be held on February 16th.

The London Gazette publishes a correction of the Christian names of Dr. David Watt Torrance, medical missionary, Scottish Hospital, Tiberias, upon whom the O.B.E. was conferred in the New Year's honours.

Dr. Charles Vaillant, the Paris radiologist, who lost both arms as the result of x-ray burns, has been promoted to the rank of Commander of the Legion of Honour.

Dr. G. M. Yevers, a Beit Memorial Research Fellow and assistant helminthologist at the London School of Tropical Medicine, has been appointed Superintendent of the Zoological Society's Gardens, in succession to Mr. R. I. Pocock, F.R.S. Dr. Yevers has been honorary parasitologist to the Society since 1921.

A PUBLIC lecture on psychotherapy and religion, arranged by the Guild of Health, will be given by the Rev. L. W. Grensted, Principal of Egerton Hall, Manchester, at the Central Hall, Westminster, on Wednesday next. The chair will be taken at 8.15 p.m. by Dr. William Brown. Admission is free; a collection will be made.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the British Medical Journal are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the British Medical Association and British Medical Journal is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the British Medical Journal, Aitology, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Mediscera, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: Baerilus, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: Associate, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

DRS. LIBA ZARCHI and CLARA SEGAL (London) ask for advice in the treatment of a woman, aged 62, who for fifteen years has suffered from persistent headaches, occurring nearly every day and lasting about twelve hours. They are not of the migraine type, but are accompanied by great depression and abdominal distension. Treatment by sodium luminal in 1-grain doses has produced no benefit.

#### DULL HAIR.

"O. P. Q." asks for suggestions for treatment in the case of two fast-growing girls, ages 12 and 17, whose hair is dull and lifeless in appearance. There is no dandruff at present, and careful brushing and washing are practised by the mother. He asks if a course of thyroid in fractional doses would be of service. The general health is good.

To a not inconsiderable extent the condition of the hair depends upon the general well-being, and as in the cases quoted there is rapid growth of the two girls the defect of the hair is to some extent dependent upon the strain put upon the body generally by this cause. When there is, in addition, dandruff—and this condition or the causes producing it have a detrimental effect on the hair—resorcin should be used as a local application. The following formula is suggested: Resorcin 1 drachm, sp. rosmarini 1 drachm, ol. ricini 1 drachm, tr. guilaine 1/2 oz., and water to 6 oz. A thorough washing of the scalp once every ten to fourteen days with a solution of green soap (sapo molis B.P.) is an advantage. It is doubtful if thyroid would prove of much assistance.

### TREATMENT OF INFANTILE PARALYSIS.

"P." describes a case of infantile paralysis involving both lower limbs from the buttocks downwards. The child is now 2½ years old; the paralysis came on suddenly about eighteen months ago. Massage and electricity have been used, and celluloid moulded splints applied. There is a slight return of movement in a few of the toes. "P." asks for advice as to treatment and prognosis.

We referred this inquiry to Mr. Muirhead Little, who writes in reply: "The only treatment I can suggest is the use of apparatus (splints, etc.) for the purpose of preventing the formation of contractions, massage to improve the nutrition of the parts, and the encouragement of any slight movements which are now possible by means of assisted exercises. Electrical treatment is not likely to be of any use. The most that can be hoped for in such a case is that the patient may be able to get about on crutches with suitable walking instruments."

### INCOME TAX.

"G. S. K.'s" car transactions have been as follows:

	Car.	Motor Cycle.
Original cost ... ..	£ 470	£ s. d. 70 0 0
Sold in 1921 for ... ..	160	30 0 0
In 1921 a similar car would have cost ... ..	650	74 10 0
New car bought (presumably in 1921) for ... ..	340	
Replaced by car costing ... ..	233	

We advise "G. S. K." to claim that the car and motor cycle should be regarded as one group or set of professional means of locomotion, and to calculate the replacement costs accordingly, thus:

Total original expenditure ... ..	£470 + £70 = £540
Deduct total amount received ... ..	£. 160 + £30 = £190
	£350

The total amount actually expended was £340 + £233 = £573, which, allowing for the increase in prices generally, does not indicate any improvement of the motor equipment as a whole, and therefore the whole of the £350 is allowable as a professional expense.

### LETTERS, NOTES, ETC.

#### DETERMINATION OF SEX.

Dr. R. A. PARKER (East Kew, Victoria) writes: Dr. R. W. Marsden, in your issue of September 30th, 1922 (p. 616), draws our attention to this subject by referring to a "surmise" of his own.

In a country district of Australia, where I formerly practised medicine, it was found by some of the residents who kept cows that if a cow fell in calf on the occasion of the first time of bulling after parturition the result generally was the birth in nine months' time of a bull calf, but that if a calf were born as the result of conception occurring at the second time of bulling, then the calf was a heifer. If conception occurred on the odd times of bulling a bull calf resulted, but if on the even times of bulling then a heifer calf was to be expected. Such a method would tend to lead to the production of about equal numbers of males and females, with a somewhat higher percentage of males as the result of more frequent conception at the first time of bulling.

Might this idea not be applied to menstruation? The production of twins of opposite sex makes this or any other theory difficult of explanation. The fact that uniovular twins are of the same sex perhaps lends support to the above idea; but where more than one ovum is shed such ova may individually each only have the power of attracting either a male or a female producing sperm, and thus twins of opposite sex may result, although heredity on the paternal side appears to be a factor.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 22.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under ... ..	...	...	0 9 0
Each additional line ... ..	...	...	0 1 6
Whole single column (three columns to page) ... ..	...	...	7 10 0
Half single column ... ..	...	...	3 15 0
Half page ... ..	...	...	10 0 0
Whole page ... ..	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

## The Cameron Prize Lecture

ON

## MICROBIC TRANSMISSIBLE AUTOLYSIS.

GIVEN BEFORE THE UNIVERSITY OF EDINBURGH, 1922,

BY

PROFESSOR JULES BORDET.

DIRECTOR OF THE PASTEUR INSTITUTE, BRUSSELS; NOBEL LAUREATE.

AMONG the discoveries which in the course of recent years have most attracted the attention of biologists is the so-called phenomenon of bacteriophagy, or, as we should preferably say, the phenomenon of microbic transmissible autolysis. From the historical point of view it ought to be recalled that we are indebted to an English scientist for the first observations on this subject. Having inoculated vaccinia on agar media Dr. Twort observed the development of a micrococcus which occasionally showed a translucent or transparent change, starting as clear spots at the margin of the colonies. Under the microscope nothing but small granules could be seen in these glassy areas. Some of the colonies showing such a degenerative change could not be subcultured. Moreover, when a pure normal culture of the micrococcus isolated from vaccinia was touched with a small portion of a glassy colony the growth at the point touched soon began to become transparent or glassy; many of the micrococci were killed and replaced by fine granules. Killed microbes were not affected. When diluted with a large volume of water the transparent growth was found to pass through the finest porcelain filters, and one drop of the filtrate, deposited on the surface of an agar tube, was sufficient to make it unsuitable for the micrococcus—that is, the micrococcus inoculated on the surface would start to grow, but would soon become dotted with transparent points. Such a disease of the micrococcus could be conveyed to fresh cultures for an indefinite number of generations. Twort also made similar observations as regards microbes isolated from the intestinal tract of several patients.

One or two years later the Canadian bacteriologist, d'Herelle, took up the subject again. His fundamental findings are closely similar to those of Twort, but he made many complementary and interesting experiments. When a mixture of broth and faeces from patients recovering from dysentery is incubated for about twenty hours and subsequently filtered, a clear fluid is obtained, possessing the wholly unexpected property of clarifying a thick suspension of dysenteric bacilli. Furthermore, a trace of such a suspension which has thus been rendered clear, added to a second suspension of the same micro-organism, brings about the same effect, and so on. Similar results have been obtained by d'Herelle for other intestinal micro-organisms, provided, however, that the faeces came from individuals who had recently suffered from a disease of the digestive tract or who had been associated with such patients. For example, d'Herelle obtained fluids exerting a lytic influence on a micro-organism belonging to the group of the *Bacillus coli*, and which afterwards was very frequently made use of by ourselves in our own experiments.

It is thus very easy to obtain an indefinite quantity of lytic fluid, working, for instance, on the *Bacillus coli*. One has but to add some drops of a previously lysed *coli* broth culture to a rather thick suspension of the same microbe in broth. After several days in the incubator the now clarified suspension is heated at 58°. This temperature kills the microbes, but does not affect the lytic agent, which is only destroyed at from 67° to 70°.

To make apparent the presence of the lytic principle in a given liquid we have at our disposal two or three slightly different methods. We may add the investigated liquid either to a turbid suspension in broth of *Bacillus coli*, in which case the principle is detected by the supervening clarification, or to sterile broth which has been freshly inoculated with one drop of *Bacillus coli* culture, in which case the bacterial multiplication is prevented, the broth preserving during one, two, or even more days, when inoculated, its original limpidity. Another very simple and striking method of detecting the lytic power consists in depositing a droplet of the lytic fluid on the central part of a nutrient agar surface which, one hour before, has been inoculated at many points with *Bacillus coli*. The tube being subsequently kept in the incubator a microbic layer soon appears and thickens over the

whole surface, except at the points which have been touched by the lytic droplet, where, the growth having been inhibited, the surface remains bare. However, some colonies may appear later on this bare spot, consisting of resistant micro-organisms, but the aspect assumed by the tube is nevertheless quite demonstrative.

How is the lytic power to be interpreted? Since the lysis is capable of being indefinitely transmitted from one bacterial suspension to another, it cannot be doubted that the principle governing the process is regenerated while acting. A very simple and easy explanation has been afforded, and is still vigorously defended by d'Herelle, who considers the causative factor of the lysis to consist in a living organism, an invisible filtrable virus, which can live as a parasite in the inside of various bacteria, thus finally disintegrating them. The first hint of this theory had been put forward by Twort, but he suggested it as a mere possibility, without being convinced at all of its correctness.

According to this hypothesis the bacterium which shows the lysis, being merely the prey of a virus, only plays a passive rôle and takes no part in the determination of its own lesion. With my co-worker Ciuca I offered a quite different interpretation. We think that the lytic phenomenon, instead of being due to the agency of an invisible parasite, is in reality an autolysis, a process of autophagy. According to our conception the microbic lysis may be regarded as the consequence of a nutritive vitiation of the bacterial metabolism, primarily induced by some external disturbing influence. This vitiation would have as an effect the production of a lytic chemical principle, a very active the lysis, and, moreover, capable of the same vitiation to new microbes belonging the lysis brought into contact with them. Among the microbes thus touched, a certain number are not immediately destroyed, and even—being still capable of multiplying before undergoing the lytic process—reproduce the lytic substance. Thus the vitiation can be unceasingly propagated, the lytic principle arousing in the living microbes the elaboration of a new amount of the same principle. If a comparison could help to the understanding of the phenomenon, we could perhaps detect a real similarity with the process of blood coagulation. Under certain circumstances—namely, when protected from the contact of foreign solid bodies such as glass, for instance, when kept in a vessel coated with oil or paraffin—a plasma may be kept fluid during a very long lapse of time without any appearance of clotting. But, if to such a fluid plasma even a slight quantity of serum is added, obtained from a previous and normal blood coagulation, the mixture quickly solidifies and liberates by the very fact a new amount of the coagulating principle, the thrombin. Thus the addition of thrombin induces the production of thrombin. Similarly, when subjected to the influence of the lytic principle, the microbe—at least, after a certain interval, during which it may be still capable of multiplying—not only shows the lytic lesion, but also, in consequence of being touched by the lytic principle, reproduces this. Assuredly, the comparison is not perfectly adequate, since the plasma cannot, whereas the microbes can, multiply, but the analogy still may be easily grasped.

Since, according to the theory, the principle is liberated by the microbes themselves, it may be anticipated that a very abundant regeneration of principle will not occur unless the microbes present be sufficiently numerous. In other words, where only a very small number of microbes are added to broth containing the lytic principle, the reproduction of the latter will be very weak if all of the microbes perish at once. As a matter of fact, unless the microbes be already very numerous at the very onset of the experiment—that is, when they are brought into contact with the lytic principle—the amount of the latter only increases considerably as a result of a certain multiplication of the microbes. But we must add that as a general rule this multiplication does take place. To be sure, when the amount of lytic principle, mixed with the microbes, is very large in proportion to the number of germs, the bacteria are, as may be expected, rapidly damaged, their multiplication being thus strongly inhibited. Still, in such cases one may frequently observe, after two or three hours at 37°, a very faint and transient opacity, which soon after wholly disappears. There are reasons to believe that in any case, when the germs are not numerous from the outset, a certain multiplication is requisite for an abundant regeneration of the principle. I shall refer to this notion again, when I shall have to deal with the resistance of the microbes and the changes that

adherents to the invisible parasite theory that this virus, being of frequent occurrence and widely distributed in the natural media, the possibility could not be excluded of its having penetrated into the humours, exudates, or abscesses, and afterwards been extracted by the investigators. Whatever may be the plausibility of such an objection, it must be confessed that it is very hard to remove it entirely. At any rate, the hypothesis of the invisible virus would be wholly refuted, and, on the other hand, the autolytic theory would be wholly unquestionable if certain facts, recently pointed out by several observers, were regularly confirmed. For instance, it has been asserted that the lytic power may start under the influence of bacterial antagonism, in a liquid containing merely two microbial different species such as *Bacillus coli* and dysenteric bacillus, or *Bacillus coli* and staphylococcus. Some observers even believe that the lytic agent may appear in a pure culture, kept during a long lapse of time under certain conditions. However, such findings are not sufficiently controlled to be unanimously accepted. Such being the case the question is not settled, and therefore we cannot avoid comparing both theories in the light of the firmly established facts, and discussing the data that can be alleged in favour of each of them.

When a tube containing some cubic centimetres of sterile broth and a moderate quantity of lytic fluid—for instance, 1/100,000 c.c.m.—receives one drop of fresh normal *coli* culture, only a very faint and evanescent turbidity occurs after two or three hours, which is frequently overlooked. Practically the liquid keeps clear and remains such during two or three days or longer. This fact would be easily understood if due to a chemical substance—to a sort of antiseptic which, naturally, could not act otherwise than distributing its hindering influence over all of the germs present. Such being the case no wonder if all the microbes are equally touched. But were the lysis the consequence of a parasite penetrating into the bacteria and disintegrating them, then it should in all probability be expected that at least some bacteria would escape and develop normally. To be sure, as I mentioned before, a transient opacity is frequently observed, but even when quite easily perceptible it disappears as a rule very rapidly afterwards, almost suddenly. The capacity of attacking almost simultaneously the totality of the developed germs could hardly be ascribed to a living virus.

It may be mentioned besides that the phenomena observed are entirely the same, whether the lytic fluids under experiment be quite fresh or previously kept during some months. The inhibitive influence exerted on the growth is identical. One can hardly believe a virus to be always ready to attack the bacterium however long may be the lapse of time during which it has been starved—that is, has not been supplied with the living bacteria representing its necessary food. When kept inactive during a long period, the virus in all probability should require an appreciable delay before eliciting again its normal aggressive abilities.

It has been unquestionably ascertained that the lytic agent does not multiply in the absence of bacteria—in sterile broth for instance. Neither does it multiply when brought into contact with killed bacteria. It may assuredly be granted that bacteria when chemically modified by sterilization may no more represent an available food. But why does the virus still not develop when mixed with living *Bacillus coli* suspended in physiological salt solution? In such a medium the lysis does not occur nor the lytic power increase. But both phenomena soon appear if some meat extract or peptone is added to the salt solution suspension, a possibility of growing being thus afforded to the *Bacillus coli*. This corroborates the notion that a certain growth of the bacterium is necessary to the operation and to the reproduction of the lytic principle, and consequently does not plead in favour of the virus theory. In fact, though not representing indisputable proofs against it, these findings at any rate tend to show that the lysis is in reality the final consequence of a vitiated bacterial evolution occurring at a certain moment in the course of the bacterial life. Most probably the fact that a sudden dissolution of the microbes may be observed after a stage of multiplication must be similarly interpreted. Thus a certain period of bacterial multiplication, however short it may be, appears as a condition necessary to the reproduction of the lytic agent. When the broth shows a weak acid reaction, or only a very slight alkaline one—a condition which is not favourable to the lysis—waves of multiplication, as Gratia pointed out, may be observed, separated by periods of partial lysis, whereas the activity of the liquid increases as a consequence of the periodical destruction of the more sensitive micro-organisms.

Another fact which must be borne in mind is that the lytic agent, which is not impaired by time, is also capable, as Kabeshima first pointed out, of withstanding the contact of substances endowed with antiseptic properties—such as acetone, ether, sodium fluoride. Of course, it could be offered as an explanation that the immediate cause of the lysis, which is thus resistant to the antiseptics, is not the virus itself, but an actively dissolving substance elaborated by it. But chemicals like chloroform, which do not destroy the lytic property, leave also quite unimpaired the capacity of the lytic agent to multiply in the presence of the sensitive bacteria.

There is a fact upon which d'Herelle always very strongly insists. When a small quantity of lytic fluid is added to a bacterial suspension, a droplet of which is, after a short interval, floated on an agar tube, the microbial layer which develops is not continuous, but shows translucent disseminated spots where an obvious lysis occurs, such clear spots being more numerous the larger the amount of lytic fluid added to the suspension. According to d'Herelle, these spots represent colonies of bacteria which are infected by the virus. The bare fact that the number of spots is in connexion with the quantity of lytic fluid made use of is not to be doubted, but does not force upon our acceptance the conclusion that the lysis is due to a virus. Another quite plausible interpretation consists in assuming that all of the bacteria are not equally endowed with the capacity to anchor very rapidly the lytic principle. Then clear spots appear only at the spots where such bacteria have been deposited, and which have absorbed a sufficient quantity. Of course, a larger number of bacteria will absorb rapidly the principle if the latter is not much diluted. It has been proved that the bacteria, even when killed, possess the property of absorbing the principle from the surrounding medium. We know that in a suspension all of the germs present are not equal respecting their sensitiveness, which in all probability depends on their ability to absorb rapidly the principle. As a confirmation of the interpretation just suggested, and which has been defended, especially by Gratia, it may be shown that the number of clear spots appearing in the experiment quoted above is in connexion not only with the concentration of the lytic principle, but also with the sensitiveness of the bacteria. The same amount of the same principle gives less numerous spots when the resistance of the culture used has distinctly been raised. By adaptation the resistance of a bacteria may increase to such an extent that there is no production of spots even under the influence of a large amount of a very powerful principle.

Experiments performed concerning the antilytic serums obtained by Ciuca and myself do not readily agree with the virus theory. When intravenously injected into a normal rabbit, the lytic agent may be detected in the blood during a rather long lapse of time—twenty hours at least. But if the rabbit has previously received under the skin or elsewhere several injections of the same fluid, the latter injected into the blood immediately disappears and cannot be recovered. This is due to the fact that the immunized rabbit has elaborated an antibody which at once neutralizes the lytic factor. Such an immune serum, mixed with broth containing the lytic principle in suitable amount, abolishes its activity, the *Bacillus coli* subsequently added being thus allowed to grow without being affected and without reproducing the lytic agent. The latter cannot be recovered, even when passages (in the presence of *Bacillus coli*) are subsequently performed from broth to broth, by which passages the antibody is more and more diluted, so that it could no more neutralize the lytic agent had the latter been reproduced. Were the lytic agent a virus, the antibody could not work like that unless endowed with strong antiseptic properties towards it. But the serum shows the same properties when previously heated at 56°—a temperature which, as is well known, destroys, as a rule, the bactericidal activity.

The study of the antilytic serums procured furthermore interesting information as regards the specificity of the lytic agent, an aspect of the problem which obviously is in close connexion with the above discussed theories. As many writers have pointed out, a lytic principle acting on the *Bacillus coli* acts similarly on closely related species, such as the dysenteric bacillus, several paratyphoid or even typhoid bacilli. But it does not work on widely different micro-organisms, such as the staphylococcus. Conversely, a principle lysing the staphylococcus does not react with *Bacillus coli* and similar microbes. Thus Gratia and Jaumann found that an antilytic serum appropriate to the *coli* lytic

principle does not neutralize in the least the staphylococcal lytic principle, and vice versa. This result cannot be brought into harmony with the view of d'Hérelle, that there exists only one type of lytic virus capable of adapting itself to different bacteria. Were such an opinion correct one and the same antilytic serum should annihilate this virus whatever might be the bacterial species under experiment. On the other hand, the result agrees with the opinion that the lytic principle is in reality derived from the bacteria themselves. In fact, principles elaborated by widely different bacteria should likewise be distinct and distinguishable by means of the corresponding specific serums; such is, indeed, the experimental result.

When two conflicting theories are to be tested, it is convenient to follow them in their logical consequences under certain experimental conditions. For example, what is likely to occur when an extremely slight amount of lytic principle is mixed with a very large quantity of living *Bacillus coli*? Logically, if the agent be not a virus but a substance, it may be anticipated that in such a case it will not be regenerated. The very slight amount of lytic agent will indeed be distributed between so many microbial individuals that each of them, being not sufficiently touched, will not reproduce the principle. This is exactly what is shown by the adequate experiment—the principle wholly disappears and cannot be recovered. Were the principle a virus, it could not be satisfactorily explained why this living being cannot multiply under such conditions, when a large number of microbes are present—that is, when the virus is supplied with a large quantity of food. Of course, in a control experiment, the same amount of principle is mixed with a rather thin bacterial suspension; then its quantity obviously increases.

But what shall we observe if, in a similar experiment, the number of the microbes, although still considerable, is somewhat lessened, the dose of principle remaining the same? Then the quantity of principle absorbed by each microbe, although still very slight, is somewhat larger than before. Then the influence of the principle will be not strongly, but perceptibly, felt, the consequence being that the microbe, moderately touched, reproduces a principle which, correlatively, is endowed only with a moderate potency. The principle is reproduced, but the properties of this reproduced principle are not identical with those of the original principle. And the difference is not of a quantitative but of a qualitative nature. The new principle thus obtained may be unceasingly and very abundantly regenerated by means of passages through successive bacterial suspensions, but it shows special characteristics, and henceforth keeps them permanently. It is a weak principle. When added to broth inoculated with *Bacillus coli* it only prevents the growth during a short period; the liquid becomes turbid after some hours, and the opacity is not markedly clarified afterwards. The weakness of such effects is not due to the fact that henceforth the liquids obtained only contain a slight amount of lytic agent. Those liquids, indeed, still work when extremely diluted. In this respect the new principle is in no way different from the strong original principle. But it works always feebly, even when present in a large dose. It actually is attenuated.

Quite similar results are obtainable by means of somewhat different procedures. For instance, if a droplet of strong lytic principle is deposited on an agar surface which has just before been inoculated on all of its points with *Bacillus coli*, the spot touched by the lytic fluid remains bare, whereas around it a normal abundant growth occurs. But after several days one may perceive that through a slow process of diffusion traces of principle invade the margin of the thick bacterial layer, thus causing there a faint clarification, a partial lysis. Of course, the amount of principle thus brought by diffusion into this zone is extremely slight in proportion to the number of microbes. Now, if some of the latter germs are removed by means of the platinum needle and inoculated into broth, a very weak principle is obtained which subsequently remains such when reproduced. Were the lytic agent a parasite, it would appear that among those parasites only the less virulent ones are capable of penetrating gradually into the bacterial layer surrounding the clear spot. This is not very likely.

A weak principle may yet be obtained even when the amount of principle is somewhat larger in proportion to the number of microbes, provided that the contact of the microbes with the surrounding fluid containing the principle be only very short, a condition which is easily performed by removing after a proper interval a droplet of the mixture and spreading it on an agar surface. Some translucent spots showing a

partial lysis soon appear, from which a culture giving a weak principle may be obtained.

Without dwelling longer on the details, we may state that from the primary strong principle new types of principle may derive, different as regards the energy of their action, and that the virus theory does not account readily for the occurrence of such modifications, the conditions under which they appear being taken into consideration. From this point of view, as well as in many other respects, the virus theory is open to criticism. But far from asserting that the problem is solved, I frankly confess that the other views, even the one which I deem the most probable, still lack indisputable demonstration. Many efforts will still be necessary; the mystery is not disclosed. I hope that this interesting problem will attract the attention of many biologists, especially of British scientists, since the study of the subject originated in your own country.

## MALIGNANT DISEASES OF THE BREAST:

WITH SPECIAL REFERENCE TO THE SUPRACLAVICULAR  
EXTENSION OF THE OPERATION.

BY

CHARLES A. MORTON, F.R.C.S.,

PROFESSOR OF SYSTEMATIC SURGERY IN THE UNIVERSITY OF BRISTOL;  
CONSULTING SURGEON TO THE BRISTOL GENERAL HOSPITAL AND  
THE CHILDREN'S HOSPITAL; EXAMINER IN SURGERY  
TO THE UNIVERSITY OF BIRMINGHAM.

In 1902 I published, in the *Bristol Medico-Chirurgical Journal*, a paper on "The results of operation in 54 cases of cancer of the breast." The paper I now publish is based on a study of all my cases of operation for malignant tumours of the breast (including the first series of 54). Of the 251 cases, 242 were cases of glandular cancer, and most of them were of the scirrhus form; 3 were cases of the very much less malignant duct cancer; and 6 were cases of sarcoma. In order to ascertain the late results I have investigated the records of 120 consecutive cases, operated on during the ten years preceding October, 1921, so that any non-recurrence would have extended over at least three years.\* There were 120 operations for ordinary glandular cancer of the breast in this period—October, 1908, to October, 1918. The 120 cases do not include one case of duct cancer which I operated on during this period, for the reason already mentioned.

### How the Investigation was Conducted.

I found in my records of these 120 cases a note as to the late results in 66. I wrote to the remaining 54 (or their doctors) to inquire as to the late results. What I have endeavoured to discover is the proportion of cases with local recurrence, because it is only this form of recurrence which could be prevented by a more extensive operation. I regard as local recurrence—recurrence in the pectoral region† (including that area of the chest wall), the axilla, the supraclavicular region, and growth attached to, but not starting in, the sternum, and even growth in the skin of the back of the chest, on the side of the operation. I have never seen any recurrence towards the upper abdomen. Recurrence in the other breast, or the opposite supraclavicular region, or axilla, or one in the mediastinum, I have not regarded as a local recurrence, as no operation short of removing both breasts, or the fatty and glandular contents of both axillae, and supraclavicular regions, could prevent it.

I have been able to trace the late results as to local recurrence as above defined in 80 of the 120 cases. Of the remaining 40 cases some died with distant metastasis without local recurrence before the end of three years after the operation, others died also during this period of intercurrent disease, and in some cases the cause of death was unknown. In many cases, as I expected, the post office returned my letter of inquiry, as they could not trace the persons to whom they were addressed. This of course most often happened with the earlier cases in the ten years' series. But I was glad to find that a considerable number of those of whom I had no note of late results did receive my letter of inquiry, and were able to reply that they had been free from recurrence for many years. And I am grateful to several medical men

\* The statistics on which this paper is based were prepared early in 1922.  
† By pectoral region I mean not only the area originally occupied by the breast, but the infraclavicular, the lateral aspect of the chest below the axilla, and the region over the sternum.

I have investigated the position of all the local recurrences I have myself observed and noted in the 185 cases of cancer of the breast included in the present series. I find that recurrence has been most frequent in the pectoral region (31 instances). In 8 the recurrence was in the skin of this region, but this skin may have been dragged into the exact position in which it was left after the operation, after its extensive undermining, to close in the large gap left by the removal of skin around the growth. Yet it was skin from some part of the pectoral area, defined in the comprehensive way I have done in the earlier part of this paper. In 26 cases growth recurred in the deeper parts of the pectoral region; in 15 of these it was not fixed to the chest wall, and in 11 cases it was so attached (ribs or intercostal muscles). In 8 additional cases, not included amongst the pectoral ones, it was attached to the sternum. There were 20 cases of supraclavicular recurrence—two-thirds of the number of pectoral ones. I was surprised to find that even with the very complete axillary clearance there were as many as 7 axillary recurrences. One of these was in the skin (which may not have been originally axillary skin) and 6 in the deeper part of the axilla, but these did not appear to be glandular. There were two recurrences in the skin of the back, between the scapulae, and one in the latissimus dorsi muscles. In no case did I ever meet with a recurrence in the downward direction—that is, between the original position of the breast and the upper abdomen—and I have never made a practice of any special clearance of the tissues in this direction. In my first series of 54 cases (not included in these 185) I did not specify the exact locality of the recurrence, but I said: "The great majority of the recurrences have been in the skin, subcutaneous tissue over the great pectoral muscles, or in the surfaces of the muscle itself." That corresponds to the result of my investigations in these 185 cases—that most of the recurrences are in the pectoral region, but there has been no recurrence in the remains of the pectoralis major or in the minor. In this first series I also noted occasional recurrence in the supraclavicular glands, and I wrote: "The fact that

in several cases the supraclavicular glands were involved: points to the advantage of a systematic removal of the glands from above the clavicle at the first operation, as Halsted now does, even though they cannot be felt to be enlarged."

I have further investigated the exact position of the pectoral recurrences which were not in the skin, to see if they frequently took place in any special locality, that could in the future be even more thoroughly cleared out than is done at the present time, or which would make it desirable to leave a tube of radium in the special locality, as has been advised should be done in the upper interspaces close to the sternum, a part which has been considered specially liable to recurrence. I have not found recurrence specially common in any particular area of the pectoral region, and indeed have only twice met with growth in the upper intercostal spaces close to the sternum. The following list will show the exact locality in the pectoral region in which growth recurred. It does not include growths on the sternum. Recurrence might be in any part of the skin; in the deeper parts it was situated as follows:

- 1, Deep tissue of chest wall just below axilla.
- 2, Two small subcutaneous nodules just below the inner end of the clavicle.
- 3, Deeper tissues in various directions.
- 4, Nodule attached to first rib just below clavicle, but only attached to rib by scar tissues, and easily dissected away.
- 5, Cartilage of third rib (and sternum).
- 6, A few subcutaneous nodules just under clavicle.
- 7, Diffuse subcutaneous recurrences.
- 8, Subcutaneous tissue.
- 9, Second and third interspaces close to sternum (and over sternum); this was removed, but it was necessary to resect the second costal cartilage, and it recurred again in six months.
- 10, This was not a recurrence, but an extension of the disease found at operation and not removable; it was in the intercostal muscle of the first interspace close to the sternum. An overlying nodule of growth attached to the first rib was removed and disclosed the deeper growth.
- 11, Nodule in intercostal space where nipple had been, and shot-like nodules in deep tissue below inner end of clavicle (removed).
- 12, Nodule under remaining strip of great pectoral, below clavicle and towards axilla.
- 13, Nodule just below clavicle, fixed to ribs.
- 14, Nodule fixed to fifth costal cartilage at junction of sternum.
- 15, Nodule on third rib close to sternum.
- 16, Nodules in region of scar, some movable, and others fixed to ribs.
- 17, Nodules fixed to chest wall under scar.
- 18, Diffuse nodules in pectoral region, some fixed to chest wall.
- 19, In subcutaneous tissues of pectoral region.
- 20, Nodule fixed on chest wall between third and fourth ribs, below axilla.

#### Mortality in the 248 Cases.

Four patients died from the operation (1.6 per cent.), and two not directly from the operation but within three weeks of it. Of the deaths due to the operation one was from sepsis in the wound. This was certainly most regrettable, but, as usual when sepsis does occur in a wound that should run an aseptic course, it was impossible to detect the flaw in the antiseptic precautions. It was a hospital case. Another of the deaths was due to an obscure condition. There was marked pyrexia, which commenced the day after the operation, and redness and swelling of the skin of the loin appeared, and the patient died on the fourth day. The wound was opened up and examined after death, and there was no trace of suppuration in it. There was one death from the anaesthetic (ether). The patient ceased breathing while I was making the first incision, and the pulse, which up to that time had been good, also failed. At the necropsy the heart was found to be the seat of fatty degeneration and there was emphysema of the lungs and granular kidneys. She was aged 66. The fourth case was a very remarkable one. The patient had great deformity of the chest, from scoliosis, and she became very cyanosed during the anaesthesia, but improved with the administration of oxygen; but the cyanosis recurred after the operation without any physical signs of disease in the chest, and proved fatal at the end of the second week after the operation, when the wound had soundly healed. This case should more correctly be regarded as a death from the late result of the anaesthetic than from the operation—if, indeed, it was really the result of either.

Of the two cases of death within three weeks of the operation, but not directly due to it, one was a woman aged 72 who died on the tenth day with primary cardiac failure, after the wound had healed. Valvular disease and degenerative changes in the heart muscles were found *post mortem*. In the other case, a woman of 62, death occurred on the nineteenth day after the operation from an obscure abdominal condition. The wound had soundly healed.

#### THE SUPRACLAVICULAR EXTENSION OF THE OPERATION.

Since I began to clear out the supraclavicular space in 1902, I have removed the fatty tissue and contained glands from

this region in 126 cases in which no glands could be felt there before operation, and in 10 cases, or 7.8 per cent., I discovered and removed cancerous glands, or at any rate cancerous nodules. This is a slightly lower percentage of cases with cancerous growth than I gave in my letter to the *BRITISH MEDICAL JOURNAL* (1921, i, 173) for the smaller number of 30 cases. I was not at that time able to search through a larger number of my records, but took 30 consecutive cases, and in these 30 cases I found 3 of supraclavicular growth, undiscovered until the supraclavicular region was opened up. A more extended search through my records (126 cases) reduced the percentage from 10 to 7.8. In one case, in which I found cancerous glands above the clavicle, I was doubtful as to their presence before operation, and therefore I have not included it amongst the 10.

In one case in which the supraclavicular space was cleared out, although the disease recurred in the other supraclavicular region, after first recurring elsewhere, yet it did not do so on the side where the supraclavicular region had been cleared. This was in a case in which the growth recurred on the sternum, and in the upper intercostal spaces on the side of the original operation, and in the other breast, and the supraclavicular region of that side. In several cases in which the supraclavicular region was cleared out at the primary operation, although a few small glands appeared there later on, yet the proportion of the recurrence then was very small compared to the recurrence elsewhere. This was so in one case of extensive recurrence in the opposite axilla and supraclavicular region, and in the pectoral region on the side of the primary growth, but only one small gland could be felt in the supraclavicular region of that side. In another case in which the growth recurred two years and three months after the operation as a mediastinal growth, and in the opposite supraclavicular region, it did not recur in the supraclavicular region on the side on which the supraclavicular tissue had been removed at the breast operation. In a third case there was recurrence, a year and nine months after operation, on the sternum and in an intercostal space in the pectoral region on the side of the primary growth, and in the supraclavicular glands on the opposite side, but not in the supraclavicular region on the side which had been cleared out at the last operation.

But when the tissues of the supraclavicular space have been cleared out, even in cases in which no growth is found there, as well as those in which cancerous glands or nodules have been removed from this region, yet growth does recur there. Out of the total of 126 supraclavicular extensions of the operation, 90 were in the 120 cases specially investigated as to recurrence. In 6 of these cancerous growth was discovered to be present above the clavicle before operation, and in the remaining 84 cases it was not discovered before operation. Out of these 84 cases, in 20 growth recurred above the clavicle. This seems very discouraging to those of us who perform the supraclavicular extension of the operation, but it is not really as bad as it seems, for if the 20 cases are analysed it is found that in 13 out of the 20 the growth was either removed (5) or was almost certainly removable (8), and could have been removed but for irremovable recurrence elsewhere; and in some of the remaining 7 cases the recurrence could, I think, possibly have been removed. So that the important fact which is evident is that in 7 of the 20 cases there was a supraclavicular recurrence which was very likely not removable, but even if so, no doubt most of the growth could have been safely removed, and a buried tube of radium might very probably have removed what was left. In the cases in which the growth could almost certainly have been removed it recurred in the form of small movable glands. In one of the cases in which it was removed I had to remove the lower end of the internal jugular vein with it, as it was firmly attached to it.

#### Analysis of Recurrent Growth in the Supraclavicular Region.

1. Some hard growth above clavicle.
2. Deep fixed growth.
3. Fixed deep nodules.
4. Cancerous gland, size of small marble, easily removed.
5. Very extensive, but just removable.
6. Small nodules which probably could have been removed except for irremovable recurrence elsewhere.
7. Nodule attached to internal jugular vein, but excised with portion of vein.
8. Hard fixed mass.
9. Several small glands which could probably have been removed, and would have been but for recurrence elsewhere.
10. Only one small gland, which could certainly have been removed, but recurrence elsewhere.
11. Growth that was removed.
12. Nodules which could probably have been removed, but recurrence elsewhere.
13. Several hard glands, probably removable, but recurrence elsewhere.

\* By recurrent growth.

14. Numerous small hard glands, possibly an extension of axillary growth, of which there were suggestive signs and symptoms; probably removable.

15 and 16. Fixed nodule behind inner end of clavicle.

17. Deep nodule, removed.

18. Very small and very slowly enlarging glands, that could most certainly have been removed.

19. Two small removable glands, but recurrence elsewhere.

20. Gland, size of small marble, under outer border of lower end of sterno-mastoid; could quite possibly have been removed.

The question arises: Can we, during the performance of the axillary part of the operation, obtain any indication as to whether or not there is cancerous growth present above the clavicle? I have examined my records of 20 cases in which growth was found above the clavicle at operation (10 in which it was not detected before operation, and 10 in which it was), and I find that I have noted that in 13 of these cases one or more glands of the subclavicular group—the glands lying above and internal to the inner border of the pectoralis minor, just below the clavicle, and around the commencement of the axillary vein—were obviously to the naked eye cancerous. In the other 7 cases my notes do not say if this was the case or not; in all these cases but one, however, there was extensive affection of the other axillary glands, and probably the subclavicular group were also affected. In some of these cases the growth had actually invaded the axillary vein, and a portion of the vein had to be removed with it. But in one case, though a typical small hard cancerous gland was found above the clavicle, there were only a few cancerous glands in the axilla, and those were of no great size. On the other hand, I have met with at least two cases in which there was a cancerous gland in the subclavicular group, and none above the clavicle. But it is certainly a significant fact that in 13 of the 20 cases in which I found growth above the clavicle the highest axillary glands were affected, and may have been in 6 of the other 7. Halsted, however, has said:—

"The axilla affords no criterion from which we might draw inferences as to the condition of the supraclavicular fossa. Sometimes with an axilla which is involved chiefly in the lower or arm part, and apparently not at all in the upper or subclavian part, we have a neck involved solely at the junction of the internal jugular and subclavian vein."

He also says:

"It sometimes happens, on the other hand, that the neck is not involved although the axilla is a solid mass of cancer. Hence it would appear that for the present our rule should be to operate on the neck in every case."

Professor Rodman of Philadelphia, in a paper he read in this country in 1904,<sup>2</sup> refers to a set of lymphatic vessels described by Poirier and Cunéo, which drain the upper part of the breast, and pass directly over the clavicle, emptying into the supraclavicular glands, and he says that in all cases in which cancer affects this part of the breast, if situated near its margin, the supraclavicular region should be explored.<sup>3</sup> Dr. Willy Myer of New York, writing in the *Annals of Surgery* in 1918 (vol. lxxviii, p. 22), says he is guided as to whether to clear out the tissue above the clavicle or not by an immediate microscopic examination of the highest infraclavicular glands—the glands lying "very near the angle, between the subclavian vein and the chest wall." If on microscopic examination there is evidence of cancerous infection in these glands, he then clears out the tissue above the clavicle. But he regards, as Professor Rodman did, the situation of the growth in the upper part of the breast as an indication for the supraclavicular extension of the operation, but only if it involves the skin. It seems to me we must be very careful how we are guided by the presence of what may seem to be cancer elements in the glands, remembering the misleading findings in cancer of the rectum, which seemed to indicate at one time that the growth involved such a considerable length of the bowel that it was necessary to excise a very great length of it.

I cannot help thinking that the pathological findings of cancer in 5 out of 6 of the supraclavicular glands examined in Mr. Parry's cases<sup>4</sup> does not indicate that in 5 out of 6 cases cancer would have developed in those glands. If so, only 1 out of 6 cases in which the supraclavicular extension of the operation is not performed would be free from supraclavicular recurrence. Halsted, who first practised the supraclavicular extension of the operation, had a very thorough microscopic examination made of the tissue removed from the supra-

clavicular region. Indeed he says: "Only those familiar with the work can understand the amount of labour implied in the statement that a given mass of fat does not contain a cancer alveolus."<sup>5</sup> And yet he found no evidence of cancer in 30 out of 67 cases. But the remaining 37 did not certainly contain cancer cells, for he says that in 14 out of the 67 the exhaustive examination of the tissue had yet to be made to determine this, and that in 14 cases glands were detected in the supraclavicular region before operation; so we must deduct 28 from the 37, and this leaves only 9 cases in 39 in which, with the most exhaustive microscopic examination of the tissue, and without any enlarged glands being palpable before operation, cancer elements, or more fully developed growths, were present, or rather more frequently than 1 in 5 cases.

Having regard to my own experience of finding a cancerous gland or glands (macroscopic) in the highest (subclavicular) group of axillary glands in 13 cases in 20 in which the supraclavicular glands were also infected, and possibly (even probably) in 6 of the other 7—but certainly in these 6 very extensive axillary gland infection—I should be inclined to limit this extension of the operation to cases in which cancerous glands are found in the subclavicular group, or to cases with very extensive gland infection, even if the subclavicular group were not involved; but looking at Halsted's experience (as quoted), which does not refer to very marked axillary involvement, I should hesitate to limit the extension of the operation to the supraclavicular region only to such forms of axillary involvement as my own experience teaches me are usually associated with supraclavicular growth. In cases of small growths in the breast with very slight axillary gland enlargement, as found on opening the axilla, I have in some cases abstained from extending the operation to the supraclavicular region; but even in cases in which only the lower axillary glands were markedly enlarged or hard, and certainly in cancerous infection of the subclavicular group, from which efferent lymphatic vessels pass to the supraclavicular glands, I shall continue to perform the supraclavicular extension of the operation. It seems to me that if by an extension of the operation—which in the majority of cases does not add to its risk—actual growth can be removed, it is better to do so rather than trust to burying in the part a tube of radium; and tubes of radium would have to be much more plentifully distributed about the country than at the present time if that is to become the routine operation for the hundreds of cases of cancer of the breast that are operated on. If, however, the condition of the patient is such that an extension of the operation is contraindicated, then the burying of a tube of radium may be indicated. I must confess that I have in some cases abstained from performing the supraclavicular extension of the operation, when the growth has not been advanced or the axillary infection marked, if the patient has had a very short fat neck, for in this condition the clearing out of the tissue in the supraclavicular region is by no means easy, and there is also a great difficulty in keeping the bandages which fix the neck dressing in good position.

It might be thought that, recognizing the fact that I have had 20 cases of recurrence in the supraclavicular region after clearing it out at the primary operation, I should abandon the extension of the operation. But we must remember that in 5 cases the recurrence could be removed, and in 8 other cases it was almost certainly removable, and would have been removed but for the presence of irremovable growth elsewhere, and that quite possibly in some of the remaining 7 cases it might have also been removed. So that the really important fact to recognize is that in 7 cases there was recurrent growth doubtfully removable. But this fact would not prevent me from undertaking an extension which, in suitable cases, hardly adds an appreciable increase of risk. We must remember the undoubted fact that occasionally the surgeon leaves behind cancerous growth which would be visible and palpable if he explored the supraclavicular region, and could be quite easily removed. I therefore still think that the supraclavicular extension of the operation should be carried out as a routine procedure, and only omitted if there is some special contraindication to it, unless the growth is very small and the axilla remarkably free from secondary growth.

Unfortunately, it is only too evident that when the surgeon does clear out from the supraclavicular region all the fatty tissue and glands he can find, yet he leaves microscopic elements of cancer which eventually cause a recurrence in a good many cases. The lesson from this is that it is most important to make the clearance as thorough as possible.

<sup>2</sup> I have not been able to verify this reference. I think it possible it refers to the paper by Poirier and Cunéo, *op. cit.* p. 115 from the upper

I have always dissected away the tissue as far inward as the internal jugular vein where it lies under the lower end of the sterno-mastoid, drawn up the fatty tissue from under the clavicle, and removed the pad of fat lying under the inner border of the trapezius. It is not an easy dissection, as the space in which to work is so small. Before I finish the dissection I push up the tissue lying deeply beneath the clavicle into the supraclavicular space, with a finger in the cleared-out axilla to bring into view any fat or glands lying there.

#### *The Extent of my Present Operation for Cancer of the Breast.*

When I published the first series of 54 cases of this operation<sup>1</sup> I did not remove the great pectoral muscle but dissected away the pectoral fascia only. I recognized that it was not easy to do this thoroughly as it was so intimately attached to the muscle, and, in order to make sure of its complete removal, in 1902 I excised the sternal portion (or the greater part of it) as a routine proceeding. I have never removed the pectoralis minor as a routine proceeding, for I see no object in doing so, though of course it is most important to take away the fat and glands lying above its upper border just under the clavicle (the subclavicular group). I have occasionally divided or removed it in cases of very extensive axillary growth, in some of which it was necessary to excise portions of the axillary vein with the growth, because division or removal of the muscle gives the best possible access to the whole course of the vessels. But if the pectoralis minor is retained it is, of course, important to spare also the internal anterior thoracic nerve, which supplies it.

In my first series of cases I was very fortunate in being able to trace every case but one. I had 30 cases in the 54 three years or longer after operation, and 9 had no recurrence, or almost 1 in 3, or 30 per cent. This is not as good as in my last series, but it must be remembered I was more fortunate in tracing my cases in the first series than in the last. Possibly the better results in the last series may have been due to the complete removal of the pectoral fascia with the muscle, possibly also to a more extensive removal of the surrounding skin and subcutaneous fat, though this seems doubtful, but certainly, I think, to the routine removal of the supraclavicular glands. In my first series of 54 cases I had no death, but I can confidently say no death in the later series was due to the supraclavicular extension of the operation.

As I have already stated, in dealing with recurrence I do not carry my incision towards the abdomen in order to remove the upper part of the sheath of the rectus or the fascia over the external oblique muscle. I have never seen a recurrence in this direction. Nor have I adopted the method of first clearing the axilla, and then later removing the breast and surrounding tissue. It seems to me that the chest wall, left exposed by the removal of the breast and surrounding tissue, can always be covered with a towel wrung out of hot saline while the surgeon is clearing the axilla; and I do not see any very decided advantage in dividing the small branches from the axillary artery which supply the breast before removing it. It is not as if one could tie one large vessel in the axilla, and thus render the removal of the breast almost a bloodless operation. The largest vessels are the perforating branches of the internal mammary artery, which are divided in the removal of the great pectoral muscle. I always begin the axillary clearance by dissecting out the fat and glands around the axillary vein above the upper border of the pectoralis minor, and as I do not remove, or even divide, this muscle in most cases, the space is best reached after the breast and great pectoral muscle have been removed.

I do not find the operation I practise, even when to it is added the supraclavicular extension, though a lengthy proceeding, a shock-producing one; only very seldom has the patient suffered from shock, even with this extensive dissection. I have had no fatality from shock in the 251 cases. In a woman of 79 for whom the complete operation for cancer of the breast was performed on one side, and an innocent cyst was dissected out of the other breast, there was no shock, and it was also absent in several women over 70 years of age. In one case, in a woman of 66, I removed both breasts, both great pectoral muscles, and cleared out both axillae at the same operation, without shock.

None of the 120 specially investigated cases were treated by x rays after operation, and yet 46 per cent. were free from local recurrence after three years, and 30.2 per cent. after five years. This compares well with the statistics of a series of

cases treated by x rays, referred to in the BRITISH MEDICAL JOURNAL (1921, ii, 411). This treatment by x rays seems a most reasonable method, for if x rays can cause the disappearance of cancer nodules, as I know from my own experience they can, how much more likely are they to destroy those cancer cells lying in the tissues which will ultimately grow and form a recurrence? But as far as the statistics quoted in the BRITISH MEDICAL JOURNAL indicate, cases not treated by x rays seem to remain as free from recurrence as those treated by it.

### CATARACT EXTRACTION FOLLOWED BY SYMPTOMS SUGGESTIVE OF SYMPATHETIC OPHTHALMIA.

BY

FREELAND FERGUS, M.D., LL.D., F.R.S.E.,

CONSULTING SURGEON, GLASGOW EYE INFIRMARY.

ON the same evening I happened to read two very suggestive papers: the first was that of Sir William Willcox which appeared in the issue of the BRITISH MEDICAL JOURNAL of January 13th, entitled "The clinical, pathological, and radiological aspects of inspection of the teeth and gums"; the other was by Professor Trug of Montpellier, entitled "Deux nouveaux cas d'ophtalmie sympathique," which appeared in the *Archiv. d'Ophthalmologie* for July, 1922.

Those two papers recalled to my memory a case which was under my care a few years ago.

The patient was a man well on in middle life who consulted me for defective sight. I found him to be highly myopic, and in each eye there were slight corneal opacities. In addition, however, he had a well marked cataract in one eye, and I advised extraction of the lens. He agreed to this and was admitted to a nursing home. On testing the eye by cultures on serum agar—a practice which I have invariably followed since 1891—I found no growth, and after a few days of systematic douching of the eye I extracted the lens. The operation passed off well, there being a slight escape of vitreous but no other untoward event. The eye was dressed in the usual manner with sterile cotton-wool and a roller bandage for the first few days, and after a period of fully a fortnight he was allowed to go home, wearing dark glasses and with instructions both to himself and to his medical attendant that the eye was to be bathed with sterile saline.

After the lapse of nearly three months I was informed by the medical man in charge that the other eye had become inflamed. I at once went to see him and found that there was a mild irido-cyclitis with adhesions of the iris to the lens capsule and a few deposits on the posterior surface of the cornea. All such inflammations are invariably the result of infection, and therefore the question at once arose as to the source of the infection in this case. I was satisfied that nothing had been introduced at the time of the operation. Everything had been carefully sterilized and no growth had been found on the culture media. On investigating matters I found that his mouth was in a deplorable condition. A number of the teeth in both jaws were much decayed and there were the usual symptoms of pyorrhoea alveolaris. It seemed to me that that condition might be the *fons et origo mali*.

He was at once removed back to the nursing home and each jaw was thoroughly cleaned; all the teeth were removed and a potassium chlorate wash prescribed. The symptoms at once began to ameliorate, and in the course of a few weeks he was able to go home entirely relieved of all acute symptoms and with good useful vision in each eye. That is some years ago, and there has been no recurrence of the acute symptoms; the only indication of the disturbance is the presence of one or two insignificant synechiae which were not broken down by the use of atropine.

Now I do not consider that this was in any true sense of the term a case of sympathetic ophthalmitis, although it presented the usual features of that disease, and I have no doubt would have ended in complete loss of vision had the source of the infection not been discovered and removed. I regard true sympathetic ophthalmitis as almost certainly due to a definite specific micro-organism which has not yet been discovered. Hence wounds, especially those which have severe wounds of the eyeball not followed by a terrible disease, and in other cases we find it following a trivial injury. Such anomalies seem to me to depend on the absence or presence of a specific micro-organism.

Broadly speaking, septic accidents after cataract and other operations on the eyeball seem to me to be readily divisible into two groups. In the first I include suppurations, which mean the introduction of some pyogenic organisms at the time of operation or before the wound has healed.

Personally I have not seen a suppurative, much less a panophthalmitis, after cataract extraction since 1891, when I had the case which made me adopt the practice of testing the conjunctiva before operating.

The second group consists chiefly of cases of extraction followed by iritis or irido-cyclitis. These, no doubt, may be due to something introduced at the time of the operation, but I am strongly of opinion that for the most part they are due to such sources of infection as obtained in the case above described, and in addition to examining the conjunctiva I have come to the conclusion that no case of cataract extraction should be undertaken till the operator is satisfied that there is no acute septic condition of the mouth, of the auræ, of the nasal cavities, of the ethmoidal cells, and of the frontal and sphenoidal sinuses.

I have not much hope from drugs, except in the presence of syphilis, in the treatment of such cases. Atropine should certainly be used, but probably the best line of general treatment is biological, as by suitable serums and vaccines, together with the removal of the source of infection. I use atropine regularly, but not indiscriminately, for it is liable to do damage by interfering with drainage, and thus may cause the retention of toxins.

## "TETANISM" IN MENINGITIS.

BY

H. BATTY SHAW, M.D., F.R.C.P.,

PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, AND TO THE BROMPTON HOSPITAL FOR DISEASES OF THE CHEST;

AND

CYRIL DEE SHAPLAND, M.R.C.S., L.R.C.P.,

LATE HOUSE-PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL.

The following case contains much that is of interest, especially from the point of view of diagnosis.

E. P., a married man, aged 37, was a mattress manufacturer, a business which brought him into contact with feathers. Although feeling far from well for a week or so at the end of October before coming to London from his place of business in the country, severe illness only commenced in London on November 1st, 1922, with sharp pain in the left side of the chest, and a shivering attack. Dr. Charles Dixon of Acton attended him and found him looking very ill and suffering from left-sided pneumonia; the fever persisted for six days, a pseudo-crisis occurring on the fourth day, the true crisis on the sixth. On November 4th, as the pulse was so weak, the patient had been given three separate hypodermic injections of 1.60 grain of strychnine sulphate; on November 5th two such injections, and on November 6th one.

From the patient's temperature reme . . . his pulse was 70 to 80, and 15th he was seized with acute pain in the right side of the abdomen, evidently due to colitis, for he passed slime and membranous material shortly afterwards for twenty-four hours. On the following three days his temperature rose to a maximum of 101°. On the morning of Sunday, November 19th, he complained of stiffness of the jaw and neck, which he attributed to sitting in a draught. The next day, however, the spasm of the neck and jaw muscles was much more marked, and, as tetanus was suspected, he was admitted to University College Hospital (November 20th).

When seen at 2.15 p.m. on that day his condition was grave. The temperature was 97°, pulse 164, and respirations 26. He lay on his back in bed with his neck held rigid; the angles of the mouth were drawn outwards, and his face presented the typical risus sardonicus; the masseters were in a condition of tonic spasm, producing absolute lockjaw; the accessible muscles of the neck were rigid, and the recti abdominis were in such a state of tonic contraction that a remarkable "statuesque" appearance was given to the anterior abdominal wall. The musculatures of the upper and lower extremities were not affected. He was quite conscious, and the reflexes were normal; although unable to speak, he conversed quite rationally by means of "hand" signs. At 5 p.m. lumbar puncture was performed, and 10 c.cm. of perfectly clear fluid was withdrawn, following which 6.5 c.cm. of a sterile 25 per cent. solution of magnesium sulphate were injected intrathecally. Examination of the fluid revealed no abnormalities microscopically, nor was any growth obtained on culture.

As it was impossible to feed the patient by the mouth a nasal catheter was passed at 5.30 p.m., but in spite of the fact that 14 grain of morphine and 1.120 grain of atropine had been given an hour previously, a violent spasm was produced directly some milk was given by this method, and was repeated at a second attempt.

Between 12 noon and 12 midnight the patient received 9.500 units of antitetanic serum subcutaneously. When seen at midnight (November 20th-21st) his jaw was partially relaxed, he was sweating profusely, the axillary temperature had risen to 104.3°, and the pulse to 130. He was kept under morphine during the night, but in spite of this the spasms of the neck and facial

muscles became more severe, and he died in a sharp spasm at 8.45 a.m. on November 21st.

The autopsy was delayed until thirty-three hours after death, because, despite the fact that there was no trace of any wound or abrasion, it was considered advisable to report the case to the coroner as one of tetanus. The left lower lobe was intensely congested and showed signs of delayed resolution of the former pneumonia; there was a small patch of fibrinous pleurisy at the right base posteriorly; elsewhere there were signs of broncho-pneumonia. The arachnoid and pia mater looked more opaque than normal, and were adherent to the dura-mater; along the lines of the cortical vessels was a greenish-yellow exudate; microscopical examination showed the presence of an intense infiltration of the meninges with polymorphonuclear leucocytes. A streptococcus was grown from the meninges, and also from the heart blood. There were no other *post-mortem* findings of note; the stools yielded no signs of the tetanus bacillus, nor was this organism discoverable in the meninges, lungs, or colon.

This case can be viewed from many different clinical points of view.

1. The case might have been one of meningitis, against which were the facts that the spinal fluid was normal; the patient was perfectly rational and conscious, and did not complain of headache or photophobia; there was no vomiting, nor were there any ocular palsies.

2. The tonic contractures might have been due to the effect of strychnine injected during the pneumonia.

3. The case might have been thought to be one of tetanus, and that the infection had taken place at the time of hypodermic medication; or one of so-called visceral tetanus, which is said to occur in patients who present no sign of external wound or abrasion.

With regard to the first possibility, at no moment did it occur to us that the patient could be suffering from any form of meningitis, or even of meningism, nor are we aware of any systematic account of tetanus, except one, in which meningitis is put forward as a condition to be diagnosed from tetanus. The late Sir G. Sims Woodhead, in vol. i of Allbutt and Rolleston's *System of Medicine*, stated that basal meningitis may sometimes be mistaken for tetanus. But had we thought that spinal meningitis might be present the negative findings of the spinal fluid excluded this, and the complete absence of cerebral symptoms excluded the cerebral form of meningitis. So far as we can find in the literature there is no description which says that the tetanus bacillus may produce meningitis, nor do we know of any observation which could give information as to the effects produced upon the meninges when intrathecal medication with magnesium sulphate is practised.

Mr. C. J. Fuller, clinical clerk, fortunately called to mind the details of a case which was similar to the present one. It was reported by Dr. L. S. Fry in the *British Medical Journal* of January 14th, 1922 (p. 56), as one of meningitis simulating tetanus. The case was under the care of Dr. W. Collier in the Radcliffe Infirmary, Oxford. In correction of the report by Dr. Fry, Dr. W. T. Collier informs us that a few organisms were found in the meningeal pus—including a very small Gram-negative bacillus and Gram-positive diplococci, and on cultivation a Gram-positive diplococcus grew; smears from the vesiculae revealed no pus cells or gonococci, nor were gonococci found in the meningeal exudate.

It is thus clear that meningitis may provoke tonic spasm of the facial muscles, producing risus sardonicus, of the muscles of the neck and of the abdominal wall; that the spasm may be constant, lasting for hours and even days; and that the spasm may become increased by irritation such as is produced by nasal feeding, etc., the patient remaining conscious throughout the illness. Such features have been held in the past to constitute a clinical picture of undoubted tetanus; this view must be abandoned. It appears to us that no reliance can be placed upon an exclusive clinical picture of tetanus, because the disease may be accurately imitated by meningitis. It is very convenient to speak of the clinical condition . . . . .cribe those cases which, though close . . . . .are shown to be quite free from any . . . . .inges. As a result of the experience gained by a study of Dr. W. Collier's case and our own it would seem advisable to coin an expression—"tetanism"—to fix the identity of those clinical conditions which simulate the very special form of toxæmia produced by the growth of *Bacillus tetani* at some spot remote from the central system, and which may be dependent upon meningitis developed as a result of infection of the central nervous system by organisms quite different from *B. tetani*.

## DIAPHRAGMATIC HERNIA OF THE ENTIRE STOMACH.

BY

J. GRANT ANDREW, M.B., C.M., F.R.F.P.S.G.,

DOCKENMOUTH;

FORMERLY VISITING SURGEON TO THE VICTORIA INFIRMARY AND VISITING SURGEON, BELLAHOUNSTON HOSPITAL, GLASGOW.

In the *British Journal of Surgery* for July, 1921, there is published a very full and interesting communication on injuries of the diaphragm, with special reference to abdomino-thoracic wounds, by C. W. Gordon Bryan, of St. Mary's Hospital, London. In this article all that has been written on the subject of diaphragmatic hernia has been reviewed, including a case of diaphragmatic hernia of the entire stomach and great omentum published by me in the *BRITISH MEDICAL JOURNAL*, 1919, ii, 412.

The following case is worthy of being put on record, as it presents some features differing from the cases already published:

On May 17th, 1921, Private R. P. was admitted to Bellahouston Hospital, Glasgow, under my care. He was wounded on September 2nd, 1918, in the left lower chest wall by a portion of an explosive shell which penetrated both the chest and the abdomen. At the casualty clearing station the foreign body was removed, and he was told that the spleen was so severely damaged that it had to be excised. He was discharged from the army on May 31st, 1919, with the wounds completely healed. He worked for nine months thereafter, but had to cease work on account of increasing weakness and of pain after food followed by vomiting. During the following year he was treated for gastritis.

On admission to the hospital he complained of pain in the epigastrium immediately after taking food of any kind, liquid or semi-liquid, and of vomiting of the food fifteen to thirty minutes after. He stated that he had vomited everything that he had taken during the last three weeks before admission, and that the vomiting had relieved the pain. His general condition was bad; he was very emaciated and exhausted, and weighed only 6 st. 7 lb. His face was earthy in colour, his cheeks were sunken, and the tongue was coated and dry. There was a healed indrawn scar in the lower left lateral chest wall, and the appearance as if a portion of the ribs had been removed. He suffered also from cough and had a muco-purulent expectoration. The percussion note was dull at both bases, though slightly tympanitic at the left base. Respiratory murmur, vocal resonance, and vocal fremitus were diminished at the right base and completely absent at the left base. Crepitation was audible at both apices. The abdomen was scaphoid in shape, and rigidity of the abdominal wall made palpation difficult. The stomach outline was impossible to make out by percussion. Pain, tenderness, and rigidity were most marked in the left hypochondriac region. As he vomited everything, even diluted milk, a few minutes after swallowing—the recumbent position made no difference—he was fed by the rectum. Nothing was given by the mouth. His pain lessened, the vomiting ceased, and his general condition slightly improved.

On May 27th, 1921, the abdomen was opened by a paramedian incision above the umbilicus. The entire stomach was found to have disappeared through a hole in the diaphragm; the cardiac and pyloric ends of the stomach met at the opening. The cardiac end appeared pouched as if the liquid nourishment had lodged there before its expulsion. The spleen was absent. The left rectus muscle had to be divided for better exposure. The stomach, which was adherent to the edges of the opening, was separated with some difficulty and drawn back into the abdominal cavity. The walls of the stomach were greatly atrophied, but bore no evidence of having been wounded; no cicatrization was visible on the serous coat. The gap in the diaphragm measured  $2\frac{1}{2}$  by  $2\frac{1}{2}$  inches, and was situated between the fibres arising from the left external and internal arcuate ligaments, and extended up to the left leaflet of the central tendon. The edges of the gap were firm, hard, and almost tendinous in character. As he was very collapsed, no attempt was made at this operation to close the opening in the diaphragm. The pleural cavity was lightly packed with flavine gauze and the ends of the packing were brought out at the upper part of the abdominal wound. As the defect in the diaphragm was closed by the packing the stomach could not for the present find its way back to the pleural cavity. The abdominal wounds were closed by through-and-through stitches. After a few days of liquid diet he was put on light solid food and relished everything he got. He had no discomfort after food and the cough became less troublesome.

It was decided (June 10th, 1921) to make an attempt to close the opening in the diaphragm from the thoracic side. An osteoplastic flap was reflected upwards, dividing the sixth, seventh, and eighth ribs in two places. This flap was temporarily stitched backward on to the thoracic wall and gave a very good exposure of the pleural cavity with its packing. The gauze was removed and the cavity disinfected. Two flaps of thickened pleura were then dissected from the undamaged portion of the diaphragm and reflected over the gap, completely closing the opening. Though the lung was collapsed it was seen to inflate partially during deep inspiration, and we decided to employ deep breathing exercises as soon as it was practicable. The osteoplastic flap was replaced in position, the periosteum of the opposing ribs stitched together, and the wound closed except for a few strips of gutta-percha tissue

for drainage. He stood the operation very well. His convalescence was uninterrupted. Both wounds were completely healed at the end of three months. The note at the base of the left lung had become slightly resonant in tone as if some expansion of the lung had occurred.

I wrote to him in December, 1922, and he answered that he was quite well except that he could not digest heavy food, and that his weight was 8 st. 2 lb.

Almost all the chronic cases published have an insidious onset. This man was wounded in September, 1918, and was operated on in May, 1921, two and a half years from the date of his wound. His symptoms were gradual in onset, probably becoming worse as more and more of the stomach passed into the pleural cavity. As in my previous case, he was treated for gastritis and the condition was not recognized until his admission to hospital. The situation of the wound and the experience gained in my former case led me to think of diaphragmatic hernia as a possible diagnosis. He was too ill to be submitted to a ray examination and, moreover, would have vomited the barium meal. His general symptoms were similar to those published in other cases—pain immediately after food or drink, and relieved almost at once by vomiting, followed naturally by extreme emaciation, anaemia, and constipation. The intestines in this case were empty and their walls greatly atrophied.

To have attempted reduction of the hernia and repair of the defect in the diaphragm at the same sitting would have been to court disaster. The abdominal route of exposure at the first operation enabled us more readily to free the stomach from its attachments to the opening in the diaphragm and to examine its condition. In my former case I closed the opening in the diaphragm from the abdominal side; in the present case this would have been a matter of great difficulty. If the case be chronic and the operation of reduction of the hernia and closure of the opening can be done at the same time the thoracic route of approach has many advantages. The thoracic route is well spoken of in the article by Bryan already referred to.

I thank the Ministry of Pensions for permission to publish the case and Dr. William Cunningham, now of Monkseaton, Northumberland, for his able assistance at both operations.

## HYDATID CYSTS OF LIVER

ASSOCIATED WITH GALL STONES AND EMPYEMA OF GALL BLADDER AND PLEURA: RECOVERY.

BY

MABEL L. RAMSAY, M.D., F.R.C.S. EDIN., D.P.H. CANTAB.,

AND

H. F. VELLACOTT, M.C., F.R.C.S.

THE case which is here reported is that of a lady who was first seen in April, 1910; she was then aged 43, and has remained more or less under medical care and treatment for the past twelve years.

## History.

When first seen she was suffering from a burning sensation shooting up to the throat and vomiting a fair quantity of acid fluid. In aspect she was a soft flabby-looking woman, and stated that she had never been very strong.

Examination showed some tenderness in the epigastrium and also in the right hypochondrium. A provisional diagnosis of gastric ulcer was made. Under dietetic and medicinal treatment the attack gradually subsided in nineteen days.

In August, 1911, she had a similar attack, this time vomiting blood. Under the same treatment the attack subsided in ten days. At this time she was also suffering from nervous symptoms attributable to climacteric changes, and required treatment until February, 1912.

In February, 1913, she had a third attack of pain, referred to the right side of the chest. Breathing was painful, but no evidence of pleurisy was found. In July, 1913, the uterus was curetted for menorrhagia. In May, 1914, she was treated for the fourth attack of pain and vomiting, which lasted a week. In June, 1916, she had a fifth attack, lasting fourteen days.

Between June, 1916, and June, 1919, she had repeated attacks of gastric pain and vomiting, each attack lasting ten to fourteen days. Thereafter she steadily improved in health, but always had to be careful of her diet for fear of so-called indigestion. At this period gall stones were suspected to be the cause of her repeated attacks of abdominal pain and vomiting. Examination of the abdomen always revealed the presence of marked tenderness in the epigastrium and some tenderness over the site of the gall bladder. On February 9th, 1922, during the night two urgent messages were received to attend this patient, who is now aged 55, but it was not possible to see her until 8.30 the next morning. On arrival at her

house she was found to be collapsed with severe abdominal pain, which, she said, began in the right hypochondriac region, radiating across the abdomen and up to the right shoulder-blade. She had had several loose motions and vomited several times, mostly a bile-stained fluid.

Examination showed marked tenderness at the level of the tenth rib on the right side, and palpation caused pain to be felt in the back. There was a sensation of a tumour in the region of the gall bladder, but this was somewhat indefinite owing to the thickness of fat of the abdominal wall. There was no jaundice; no tenderness over the appendix. The breath sounds over the chest were normal. Temperature 99°, pulse 100.

A provisional diagnosis was made of a distended gall bladder (probably mucocele) with passage of gall stones into the common duct. Operation was advised, but the patient decided to wait events for a day or so. She was therefore treated on February 11th and 12th with fomentations and bromides, with no relief to symptoms of pain. Temperature 98°, pulse 100.

On February 13th, finding she was not improving, and before agreeing to an operation, she desired a consultation, and accordingly was seen by Mr. H. F. Vellacott. He agreed with the diagnosis made and advised immediate operation. The patient now agreed to submit to operation and was removed to a nursing home.

#### First Operation.

The same day, at 4 p.m., an operation was performed, Mr. H. F. Vellacott assisting. Dr. Rosa Bale gave the anaesthetic, first inducing with chloroform, followed by ether. An incision was made splitting the right rectus. On opening the peritoneum a large distended gall bladder was exposed and found to be full of small calculi (135 were subsequently removed). The gall bladder was adherent to the colon, from which it was freed. No stones were found in the common duct. As some difficulty was experienced in removing some stones in the cystic duct the gall bladder was opened. On opening the gall bladder a number of stones were removed and at the same time the liquid purulent contents came away together with the whole lining of the gall bladder, which was gangrenous—in fact the examining finger went through the necrotic muscular and serous coats of the gall bladder. The gall bladder was then resected, the cystic artery being tied separately. The appendix was then sought for and removed. The stomach, which was very much distended, was examined for gastric ulcer, but none was found. The wound was stitched up, a tube and gauze drain being put down to the site of the stump of the cystic duct.

*Progress.*—The patient made a rapid recovery, and was digesting an ordinary diet at the end of a week. She left the nursing home at the end of four weeks, having had a normal temperature for three weeks. The only complication was a slight abscess, which healed up when some calgut came away. Whilst in the nursing home a report was received from the night nurse that the patient had had a rigor on the seventeenth day after her operation, and some vomiting; the temperature was 99°, pulse 100. Under treatment of hot drinks and a dose of aspirin the attack subsided, and it did not recur again. Not much notice was taken of this attack at the time, as the wound was healing well, and the general condition was otherwise quite good. It was regarded as of nervous origin. She left the nursing home on March 11th.

After being at home convalescing for three weeks, an urgent message was received on April 1st, seven weeks after the operation of cholecystectomy, because the patient had had a rigor, and also complained of excruciating pain in the right shoulder and neck; she was aching all over. Temperature 103°, pulse 110. Examination of the chest revealed nothing. The abdominal wound showed no tenderness. As influenza was in the house the attack was thought to be influenzal.

The next day the pain was in the left side of the chest. The following day the pain radiated down the right arm and right side of the neck (phrenic nerve pain). Examination of the chest revealed nothing.

On April 9th, examining the chest daily, it was noted that there was gradual diminution of breath sounds and increasing dullness up to the level of the seventh rib posteriorly. After the original rigor the temperature ranged from 99° to 99½°; the pulse, however, was very quick—110, 120, 140, at times, accompanied by profuse perspiration. A diagnosis of subphrenic abscess was made.

On April 11th Mr. Vellacott again saw the patient and he performed an exploratory puncture, first in the tenth intercostal space, and, nothing being found, then posteriorly near vertebra, and pus withdrawn—the first: syringful being pure pus and the second of a tomato colour. The patient's condition was very grave, and she was again removed to the nursing home.

On April 12th her condition rapidly became much worse and pain was very severe. She was gravely collapsed. Temperature 105°, pulse 120 to 133.

#### Second Operation.

Under gas and oxygen, given by Dr. Rosa Bale, Mr. Vellacott resected the tenth rib. After sewing the pleura to the diaphragm an incision was made into the liver. Large quantities of dark blood and clots escaped. The abscess was not at first found. Sinus forceps were pushed into a large abscess in the right lobe of the liver, and about three pints of pus were evacuated. A large drainage tube was put in. Examination of the pus revealed the presence of numerous cysts.

A diagnosis was made of hydatid cyst of liver, and Dr. Wordley, pathologist to the South Devon and East Cornwall Hospital, reported that he had found numerous hooklets.

*Progress.*—The patient was very critically ill for the next fortnight, but the tongue began to clean and appetite slowly came

back. On April 21st it was necessary to aspirate the right base, and about 8 ounces of serous fluid were withdrawn. The wound discharged large quantities of pus and fragments of cysts and cyst wall. It was treated by frequent irrigations of Dakin's fluid (two-hourly). Her general condition, however, was not satisfactory; she had an irregular temperature—102° to 103°—with a rapid pulse of 120 to 130, and a respiratory rate of 30 to 50. Dullness of lung increased and fluid was diagnosed as present up to the level of the sixth rib. Believing she was going to die, and wishing to be at home, she refused to remain in the nursing home, and was consequently removed by ambulance to her own home on May 3rd. That evening the temperature was 103°, pulse 126, respirations 40.

On May 4th she permitted an aspiration, and 40 ounces of purulent dark bile-stained fluid were removed. This gave some relief. Examination of the fluid by Dr. Wordley showed no hooklets to be present. She consented to be operated on again.

#### Third Operation.

On May 5th, under gas and oxygen administered by Dr. Rosa Bale, the third operation was performed, assisted by Mr. Vellacott. The eighth rib was resected and from the pleural cavity a few ounces of pus were drained. Considering her grave state she stood this operation very well. A large tube was left *in situ*. That evening the temperature fell to 97.6°, pulse 110, respirations 25.

From this date she began rapidly to improve and the temperature never rose again. The pleural sinus was healed six weeks later and the lung had recovered from its collapse. By June 14th she was able to be out of bed, and ten days later to go for a drive. The sinus in the liver is now reduced to about 1½ in. and admits a fine probe. Some pus still discharges at times, but it is lessening. She is able to perform some of her household duties and goes out for walks daily.

A large measure of the success attained in this case was due to the patient being given gas and oxygen (Boyle method) by Dr. Rosa Bale, which thereby reduced the severe shock of the last two operations. The original source of infection has not been ascertained.

## THE RADIATION OF PAIN IN LESIONS OF THE FALLOPIAN TUBE.

BY

MAURICE MARCUS, M.B., B.S. LOND.,

LATE HOUSE-PHYSICIAN, KING EDWARD VII HOSPITAL, CARDIFF.

THE physical signs of diseases of the Fallopian tube have been described with great minuteness, but less attention seems to have been paid to a description of the subjective symptoms, and particularly of the radiation of the pain which occurs in these conditions.

The pain arising from an affection of the tube is rarely distinguished from that due to involvement of the neighbouring parietal peritoneum. Thus, as symptoms of salpingitis, are mentioned pain and tenderness on pressure in the iliac fossa, in the mid-line in the hypogastrium, and also posteriorly in the loin—that is, the pain of salpingitis is confused with that due to the local peritonitis. But the Fallopian tube, like other hollow viscera, reacts to disease by pain which is referred to the skin over an area dependent upon the spinal segments from which it receives its innervation. From a consideration of the cutaneous hyperaesthesia in a case in which the tube was involved, Head<sup>1</sup> considered these to be the eleventh and twelfth dorsal and first lumbar segments. This view appears to admit of some modification, for in the cases described below of various lesions of the Fallopian tube the pain complained of was felt in an area wider than that governed by these three segments. It was felt in the loin, in the iliac fossa, and was said to pass down the anterior surface of the thigh to the knee. This distribution appears to be peculiar to the Fallopian tube, and its recognition may be of value in arriving at a topographical diagnosis.

*Case 1.*—A married woman, aged 21, complained for some time of pain "like a toothache" of great severity in the left iliac fossa. She suffered also at times from pain of slighter intensity round the umbilicus and in the right iliac fossa. At operation (by Dr. Tenison Collins) there was found a large left-sided hydrosalpinx and cystic ovary, and a long appendix.

The following cases show the typical radiation of pain down the thigh.

*Case 2.*—A married woman, aged 22, complained for a year of irregular menstruation, menorrhagia, metrorrhagia, and dysmenorrhoea. She suffered from pain in the right iliac fossa, which passed down the front of the thigh as far as the knee (information volunteered); occasionally pain was felt also in the small of the back. The pain was very severe, shooting in character, and sometimes lasted for the whole day. Pain was also felt in the

left iliac fossa, but this was not so severe nor did it radiate elsewhere. She had had two miscarriages. On examination (by Dr. Tenison Collins) the uterus was found to be anteverted, the right tube was very much thickened and extremely tender on palpation, and there was shortening of the right broad ligament. The left tube was thickened, but not to such a degree, nor was it so tender.

**Case 3.**—A married woman, aged 40, suffered from abdominal pain for nineteen years. A week before admission to hospital she complained of very severe pain which started in the right iliac fossa and passed down the right thigh to the knee. She was tender over the whole of the lower abdomen. At operation (by Professor Ewen Macleann) free purulent fluid was found. The right tube was thickened and distended with pus. There was a condition of general inflammation in the pelvis, involving the appendix and the left tube, which was secondary to the right tube.

**Case 4.**—A married woman, aged 45, multipara, had her last menstrual period six weeks previous to admission. Two weeks before admission to hospital, for one day, she passed blood, pale in colour, per vaginam. Four days after this, while at stool, she complained of a sudden agonizing pain in the left iliac fossa, and a little way down the left thigh. Below this point, down to the knee, she felt a sense of numbness. On the following day she passed blood and clots from the vagina. At operation (by Dr. Tenison Collins) a ruptured left tubal gestation was found.

**Case 5.**—A female patient, aged 50, admitted to hospital as an emergency case, complained of severe pain in the hypogastrium, in both iliac fossae, and down the anterior surface of both thighs, the pain being most severe in the left iliac fossa. At operation (by Mr. H. Geary Grant) a bilateral salpingitis and diverticulitis was found. The left tube was the more inflamed, and had given rise to the diverticulitis (sigmoiditis).

**Case 6.**—A married woman, aged 26, complained of dysmenorrhoea, metrorrhagia, and leucorrhoea for the last three months. Nine days before admission to hospital she felt a sudden pain low down in the right iliac fossa, passing down the right thigh on the anterior and outer side of the limb to the knee. She complained of a burning pain on micturition since the onset of the pain; she vomited for the first time five days after the onset of the attack. On examination, a tender fluctuating lump was felt in Douglas's pouch on the right side. At operation (by Dr. Tenison Collins) a right pyosalpinx was found, much pus escaping; the left tube was inflamed.

In spite of the difference in character of the lesions—namely, acute salpingitis, pyosalpinx, and ruptured tubal gestation—the pain complained of in these cases had as a common feature its origin in the iliac fossa and radiation down the anterior aspect of the thigh to the knee. The uniformity of this distribution is against the hypothesis of an "overflow" of the stimulus from the tube through the last dorsal and first lumbar spinal segments to the lower lumbar segments; it suggests rather that the Fallopian tube is represented in the spinal cord by the eleventh and twelfth dorsal and first, second, and third lumbar segments, the first three lumbar posterior roots innervating the area of the skin from the groin to the knee, on the anterior aspect of the thigh.

#### Summary.

Lesions of the Fallopian tube cause pain which, arising in the iliac fossa, is referred down the front of the thigh to the knee. This distribution of pain is significant of an involvement of the tube, and appears to be of diagnostic value. It suggests, further, that the tube is represented in the spinal cord by the eleventh and twelfth dorsal and the first three lumbar segments.

In a note contributed to the *Lancet* the above observations were used to establish a differential diagnosis between appendicitis and inflammation of the right tube, the difference being that the pain of appendicitis starts usually round the umbilicus, and, felt later in the right iliac fossa, does not pass below the groin.

I wish to thank Dr. Tenison Collins, Professor Ewen Macleann, and Mr. H. Geary Grant for permission to publish these cases, and Dr. Alexander Hastings for allowing me to use his notes.

It was decided (June 1922) to open the diaphragm, vol. 16, Part 1, pp. 89, 101. 2 Marcus, M.: opening in the diaphragm, vol. 16, Part 1, pp. 89, 101. 2 Marcus, M.: flap was reflected upwards, ribs in two places. This flap was reflected on to the thoracic wall and gauze of Natural Science and pleural cavity with its packing. The gauze was cut 5th to 7th, cavity disinfected. Two flaps of thickened pleura were dissected from the undamaged portion of the diaphragm and reflected over the gap, completely closing the opening. Though the lung was collapsed it was seen to inflate partially during deep inspiration, and we decided to employ deep breathing exercises as soon as it was practicable. The osteoplastic flap was replaced in position, the periosteum of the opposing ribs stitched together and the wound closed except for a few strips of

## A CASE OF RITTER'S DISEASE.

BY

RONALD McD. CAIRNS, M.B., Ch.B.,

SENIOR HOUSE-PHYSICIAN, ROYAL INFIRMARY, LEICESTER.

The following case of an exceedingly rare disease seems of sufficient interest to warrant its being placed on record:

The mother, a primipara, had always enjoyed good health and presented no abnormality throughout her pregnancy. The child, a male, was born after a somewhat difficult labour, which demanded instrumental interference, but at birth the baby appeared perfectly normal and did not exhibit any cutaneous abrasions, and incidentally the skin, in general, was quite healthy.

The child thrived, but on the seventh day my attention was attracted by a flaccid bulla, about two inches in diameter, resembling the lesion in pemphigus foliaceus. It had arisen during the night, was situated in the left pectoral region, and but for the fact that the surrounding skin did not exhibit any local reaction it looked suspiciously like the blister from a scald, but no history of exposure to heat could be obtained. The temperature was normal and there were no constitutional symptoms.

On the following day the lesions had spread; they involved practically all the left pectoral area and extended over the left shoulder. The bulla had burst, exposing a hyperemic dermis and large pieces of the affected epidermis were peeling off. Under the remaining raised edges of the skin there were small collections of serous effusion, showing a very slight degree of turbidity.

There was still further extension on the ninth day, the method of spread consisting of the actual increase in size of the existing affected areas and the formation of new bullae. The left upper arm, practically as far as the elbow, was now involved, but between the lesions patches of comparatively normal skin still showed. The child was irritable, crying almost continuously, refused both breast and artificial feeding, and was obviously wasting, but the temperature was still normal and the motions regular and normal.

On the tenth day hyperemia of the skin over the nape of the neck and the occiput appeared, and by evening a bulla had appeared in this position. This formed a marked contrast to the primary blisters, which had shown no initial reddening, nor a reaction areola. The new bladder-like swelling contained seropurulent effusion and the fluid in the other lesions was assuming this character also. The right side of the chest and right upper arm became affected on this day. The elbows were practically clear, but the hands, particularly the dorsal aspects, and the wrists showed the typical bullae. There were, in addition, a few reddened patches on the cheeks and brow, one in the neighbourhood of the umbilicus, while below the knees the affected skin was being shed in large moist flakes. Almost all the surface of the back had desquamated, and in the arm in particular, but to a certain extent in all the larger lesions, the exposed dermis was acutely inflamed, yet exhibiting no signs of necrosis, being quite dry in the centre, with no appearance of any exudate.

On the following day, the eleventh, and the fourth day from the onset of the disease, the child died. The affected parts had still further progressed and the child was very much wasted, death evidently being due to marasmus. Even up to the end there was no fever, but on the last day the temperature was subnormal.

The bowels were regular throughout and no internal complication arose. Ung. hydrarg. ammon., caron oil, ung. sulph., arsenic, and soothing baths were all tried, but proved equally useless in attempts to arrest the progress of the disease. The mother made an uninterrupted recovery.

This disease has been variously described as Ritter's disease, dermatitis exfoliativa neonatorum, and pemphigus neonatorum, and Ritter von Rittersheim, Elliot, and others have described this non-contagious affection. In founding institutions on the Continent it is comparatively common, nearly 300 cases occurring in the founding asylum at Prague during a period of ten years, but down to 1900 no cases had been recorded in this country. Recently, however, I believe, one or two isolated cases have been noted.

The etiology is most obscure. Some regard it as a form of pemphigus foliaceus, some consider it impetiginous, others attribute it to some abnormal condition of the maternal milk, while still others look upon it as an exaggeration of the natural exfoliation of the newly born. Sepsis has never been found to be responsible. It usually occurs between the first and third weeks of life, but occasionally the onset is delayed until a month or even five weeks after birth.

The condition presents such a typical and unusual picture that little difficulty is experienced in diagnosis. Treatment, beyond the protection of the blebs by powders and the prevention of secondary infection by suitable dressings and soothing baths, appears to be unavailing.

In Ritter von Rittersheim's series the mortality was practically 50 per cent., but some place it at an even higher rate. The sporadic cases certainly appear to be more fatal.

I much regret my inability to obtain a post-mortem examination and a bacteriological report on the exudate exuded from the unbroken bullae.

## The FitzPatrick Lectures ON THE POST-HIPPOCRATIC SCHOOLS OF MEDICINE.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS  
OF LONDON,

BY  
R. O. NOON, M.D., F.R.C.P.

[Abstract.]

(Concluded from page 145.)

### THE METHODISTS.

THE school of the Methodists seems in a sense to occupy an intermediate position between the opposing schools of the Dogmatists and Empirics. This name of Methodist is doubtless more familiar to English ears as the sobriquet jestingly given by a Christ Church undergraduate to the small group of friends who gathered round the brothers Wesley in Oxford in the middle of the eighteenth century on account of their regular manner of life and behaviour. The name as originally given had of course reference to intellectual and not moral qualities. In any case it was not very appropriate, though the founders of the school did perhaps commit themselves to a more definite and precise theory of disease than either the Dogmatists or Empirics.

This school reduced medicine to very simple terms, which may remind us in some ways of homeopathy, for in therapeutics they adopted the principle of "contraria contrariis curantur," which is analogous though antagonistic to the system of Hahnemann. According to the Methodists the body consisted of atoms and pores, a doctrine derived from Epicurus. To the atoms they paid but little attention, concentrating themselves on the pores. Now these pores were said to be either in a state of too great contraction or too great relaxation.

The foundation of the school of the Methodists synchronized with the migration of medicine from Alexandria to Rome as the centre of intellectual activity, and the entry of Greek medicine into Rome had been accomplished by the well known and popular physician Asclepiades of Bithynia, who had adopted the doctrines of atomism from Democritus and Epicurus. Themison of Laodicea (fl. 50 B.C.), a pupil of this Asclepiades, founded the school of Methodism. Though, like his master, he followed the doctrines of atomism, unlike Asclepiades he concentrated his attention entirely on the pores, paying hardly any heed to the atoms. For the Methodist generally, acute disease was a state of contraction (status strictus), while a chronic disease was a state of relaxation (status laxus). As regards therapeutics, there were for the Methodists only two indications: (1) to relax the pores when there was a constriction, (2) to constrict them when there was a relaxation. What could be simpler? Among the therapeutic agents which were thought to have the desired effects were:

#### Relaxing Agents.

1. Venesection; but they practised this with caution, because "bleeding" tended to draw off the finer, the more vital atoms first, leaving the coarser ones behind.
2. Cupping; of this they made frequent use—sometimes they would cover nearly the whole body with cupping glasses, as they paid no attention to the part affected.
3. Softening plasters.
4. Warm drinks.
5. Diaphoretics.
6. Warm air.
7. Sleep.
8. Exercise carried to the point of fatigue.

#### Constricting Agents or Astringents.

1. Darkness.
2. Cool air.
3. Cold water and acid drinks.
4. Decoction of quinces.
5. Powdered chalk, lead plaster.
6. V.

During the first three days of an illness they enjoined strict abstinence; then they administered food only every other day. Remedies were not given till the third day. During the days of abstinence the patients only washed their mouths with water and drank a little; apart from this they were covered with plasters and wool steeped in warm oil if the disease was one in which the pores were contracted, and in

cold oil if the disease was one in which the pores were relaxed.

By means of these summary methods of diagnosis and cure the Methodists thought they could dispense with all further research. They made no inquiry into causes whether remote or proximate, for, from the moment the causes had produced their effect—that is to say, from the moment the disease was formed—it was this, they said, which one had to cure. It was from the disease itself, they said, its nature, character, and cause, that one had to find the indications for treatment, and not from anterior circumstances, which had no influence; and the nature of the disease consisted in having the pores too much constricted or too much relaxed.

The best known member of this school, and by some regarded as the real founder of it, though an absolute charlatan, was undoubtedly Thessalus of Tralles. He was the son of a weaver, which occupation he followed in his youth, and had enjoyed none of the elements of a liberal education; from this resulted the pride of ignorance and scorn for the observations of his predecessors. He considered that medicine could be learnt in six months. He reversed the famous aphorism of Hippocrates that "Life is short and Art is long" by saying that "Art was short and Life was long"! On a monument in the Appian Way he styled himself "Conqueror of Physicians," and he wrote to the Emperor Nero saying that his medical predecessors had contributed nothing to science—the kind of statement which Nero might well have appreciated. So little did he know of Greek that he accused Hippocrates of causing the death of his patients by overfeeding them.

"I have," said Thessalus, "founded a new sect, which is the only true one, being obliged to do so because none of the physicians who have preceded me have found out anything useful for the preservation of health nor for banishing diseases, and Hippocrates himself has uttered many harmful maxims on this subject."

By dint of great flattery Thessalus insinuated himself into the houses of the great. According to Galen, who was, however, the bitter enemy of the Methodist school, the manners of Thessalus were submissive and slavish, very different from those of the ancient physicians, the descendants of Aesculapius, who gave commands to their patients like a general to his soldiers or a prince to his subjects. Thessalus, on the contrary, obeyed his patients like a slave his master: if his patients wished to bathe he let them do so; if they wanted to take ice or snow he gave it them. Naturally Thessalus attracted a large number of pupils, mostly from the artisan class, who were anxious to become doctors in six months; he himself wrote five large volumes which would require almost that length of time to read through.

Of a far higher calibre was Soranus of Ephesus, who may be regarded as one of the chief ornaments of the Methodist school. He came to Rome in the time of Trajan and Hadrian (fl. A.D. 93-138). He was the first of the school to offer a plausible reason for the rejection of the use of purgatives—namely, that they got rid indiscriminately of humours which were wholesome and those which were vicious. He always used venesection in pleurisy, because it clearly arose from a status strictus. He wrote a book on gynaecology which showed that he had a wide knowledge of anatomy, a subject as a rule despised by the Methodist school, and his ideas on anatomy seemed to have been based on human and not merely on animal dissection, as had been the case with most of his predecessors. The great theologian Tertullian spoke of him as "methodicae medicinae instructissimus," and his reputation lasted well on into the Middle Ages.

We should know but little of the Methodist school were it not for the writings of Caelius Aurelianus, who lived in the fifth century; he was a native of Sicca, in Numidia, but practised and taught in Rome. Like most other members of the Methodist school his education had been very imperfect, and this perhaps explains the barbarism of his style and his complete ignorance of the Greek language. On the other hand, no ancient author has more clearly set forth the diagnosis of each disease, and it was a fortunate circumstance that in the Middle Ages the monks selected him before all others for their guidance in the treatment of disease.

As examples of acute diseases which depend on constriction, Caelius Aurelianus gives us (1) madness, (2) lethargy, which involved a stronger constriction than madness, (3) catalepsy, (4) pleurisy and pneumonia, (5) tumours. Chronic diseases depending on constriction were (1) headache, (2) giddiness, (3) asthma, (4) epilepsy, (5) jaundice, (6) obesity, (7) suppression of the catamenia, (8) melancholy, (9) paralysis, (10) phthisis, (11) colic.

As an example of acute disease caused by relaxation he gives cholera, and of chronic diseases haemoptysis and diarrhoea, excess of the catamenia, and wasting.

Since these two general states of the body were sufficient to guide the physician in the knowledge and treatment of disease all etiology became superfluous, for there is no object in knowing the cause of constriction, for instance, so long as we are able to cure it.

The Methodist school certainly possessed the merit of endeavouring to cure disease by the simplest measures, such as air and food. In order to make use of air for the purpose of relaxing the pores they put their patients into rooms which were very light, moderately warm, and large. When, on the other hand, they wanted to have the constricting effect of air they placed their patients in rooms which were dimly lighted and very cool. They also paid great attention to posture in bed, and considered the sort of covering patients ought to have, whether they should sleep on a mattress or on a bed of feathers, whether the bed should be large or small, and its relation to the windows. In a word, they were most particular about all such things as other physicians passed over more lightly.

The school of the Methodists was astonishingly successful, at least in gaining students, partly, no doubt, because their system could be acquired in a very short time; in fact, it demanded the minimum amount of knowledge, and so it satisfied the natural appetite of the human mind for generalizations, which the Empirical school had done nothing to supply. Finally, it occupied an intermediate position between Dogmatism and Empiricism, appearing to unite the advantages of both schools without the inconvenience of either.

The philosophy which had most influence upon the school of the Methodists, and which in fact formed their intellectual background, was that of Epicurus. He was born in the island of Samos about 342 B.C., some two hundred years later than Pythagoras. At the age of 18 he went to Athens and began life there as a teacher of grammar, until his attention was drawn to philosophy, owing, it is said, to the inability of his teachers to explain what Hesiod meant by chaos. At the age of 35 he purchased for 80 minae his famous garden in Athens, and there he taught for the remainder of his life, till his death at the age of 72. Epicurus was one of the most prolific of Greek writers, and is said to have written some three hundred volumes. He prided himself on being self-taught, and boasted that he was entirely independent of all his predecessors, yet it is quite obvious that he was largely indebted to Aristippus and the Cyrenaic school of pleasure on the one hand and the atomic theories of Democritus on the other. He took no part in political affairs, his maxim being "to live secluded." The main purpose of the philosophy of Epicurus was the moral life; thus, physics were regarded as merely ancillary to ethics, which were the beginning and end of the Epicurean teaching. Thus he regarded philosophy as part of the daily business of speech and thought with a view to securing a happy life. According to Epicurus it was not necessary to have read deeply or thought profoundly; literature and education were often more of a hindrance than otherwise.

The popular conception of Epicureanism as encouraging an unrestrained luxury, and teaching unwise facts, and is due to or to show us the kind of life advocated by Epicurus. In writing to a friend he says: "For myself I can be pleased with bread and water, yet send me a little cheese in order that when I want to be extravagant I may be." He is also responsible for the saying, "It is more blessed to give than to receive." To Epicurus the world presented itself as a mechanism, and within the limits of this mechanism it was the business of man to arrange his life as well as he could, but it was not necessary for him to know more of this mechanism than that on which his own weal or woe depended. So long as one realized that everything had natural causes it mattered little what the causes were. He adopted the atomic theory of Democritus because this harmonized best with his ethical individualism.

Although the doctrines of Epicurus never took so great a hold upon the ancient world as Stoicism, yet his immediate disciples adopted and followed his teaching with scrupulous conscientiousness, and they became devoted to their master in a way which has been hardly equalled in ancient or modern times. They are said to have committed his works to memory; they had his portrait engraved upon rings and

drinking vessels, and they celebrated his birthday every year. Athens honoured him with bronze statues, and the number of his pupils and friends is said to have exceeded the population of whole cities.

It is well to remember that at the time when Epicurus was living at Athens the Grecian world had seen the downfall of Thebes, the exile of Demosthenes, and the shipwreck of the whole Hellenic State system. Political freedom having to a large extent disappeared, the philosophers endeavoured to establish an internal freedom based upon ethical principles and to maintain it in spite of outward oppression. It was this inward freedom which the Epicureans no less than the Stoics set themselves to supply.

It is not to be imagined that the average physician of the Methodical school busied himself much about the Epicurean or, indeed, any other philosophy; but he was none the less surrounded by it, as the ordinary man is enveloped in the atmosphere, about the weight and composition of which he is not concerned to inquire. What we have specially to note is that the Epicurean philosophy, by its close concentration on the moral life of man, together with its inadequate and most superficial way of dealing with physics, helped to promote the decidedly crude and superficial way of regarding disease which we have seen to be characteristic of the school of the Methodists.

### THE PNEUMATISTS.

Though in some ways the least influential and certainly the most short-lived of these post-Hippocratic schools of medicine, their very name has a certain fascination about it which draws one's thoughts to the schools of philosophy.

The Pneumatists may be regarded as an offshoot of the Dogmatists, who began to take on this name when the sect of the Methodists was at its zenith. Physicians who did not want to follow the Methodist school embraced that of Pneumatism so as to have solidly established principles which they might oppose to the Methodists. For, unlike the Methodists, the Pneumatists believed much in dialectic and regarded it as indispensable to the perfection of science. The name "Pneuma" was given by them to what they regarded as an active principle which was the determining factor of health and disease. Platonic theories had already laid the foundation of the doctrine of this aerial substance, but Aristotle gave the first clear idea of it when he described the way in which the pneuma is introduced into the body and the circulatory system.

The doctrine was still further developed by the Stoics, and they exercised a great influence over the Pneumatists and so upon the further evolution of medicine. They were of opinion that the aerial substance passed from the lungs into the heart and arteries and was then disseminated throughout the body. The Pneumatists maintained their theories with the greatest enthusiasm and pertinacity; Galen says of them that they would rather have betrayed their country than abandoned their doctrines.

The founder of this school was Athenaeus of Attalia in Cilicia, who practised in Rome in the reign of Claudius, about the middle of the first century. In his teaching Athenaeus maintained that the pneuma was the World Soul, the living Self-consciousness, and who was also the creator and framer of all matter. Its unhindered movement was in the last resort the cause of all physiological and pathological happenings. As a Stoic Athenaeus adopted all the doctrines of the Peripatetic school, but he developed the theory of the elements more or less after the manner of the Methodists.

It was from this school that there emanated some curious teaching about the pulse at different ages; thus, in the newborn the two short syllables of a verse—a short systole and a short diastole; in older persons the pulse is like a trochee, while in still older people the pulse with a long systole and long diastole becomes like a spondee.

Far better known than Agathinus was his disciple Archigenes of Apamea, who practised medicine at Rome in the time of Trajan, and enjoyed among his contemporaries a great reputation which endured for several generations. Like the Stoics Archigenes placed the seat of the soul in the heart, which not unnaturally made the explanation of the sensory nervous system a matter of considerable difficulty for him. His doctrine of the pulse was famous in antiquity, and he described eight different kinds of pulse according to its size, force, velocity, frequency, fullness, regularity, equality,

and rhythm. Each of these species was divided into several varieties.

Archigenes made use of a large number of drugs, mostly of a mild variety, preferring mild laxatives to drastic purgatives. At the height of the disease he had recourse to warm fomentations, especially to sponges soaked in warm water, in order to lubricate the pores and favour coction. He gives an excellent account of dysentery, which he attributed to ulceration in the large intestine, and he prescribed for it preparations of opium and astringents. He further described the signs for recognizing an abscess of the liver, and explained its formation and termination. With regard to insanity, Archigenes, like most Greek physicians, showed remarkable enlightenment. Seeing the priests of Cybele scampering and flagellating, and cutting themselves after their manner, he said, "They are insane; do not leave them to those bloody gods of the East; send them to me." His treatment of the maniac was to feed him up and soothe him with music. On the other hand, so little consistent is the mind of man, he sometimes in his treatment had recourse to amulets and other methods of superstition.

Of the same school and about contemporary with Archigenes was Aretaeus of Cappadocia, to whom we are indebted for some of the best medical writings which have come down to us from antiquity. In all probability he flourished in the second half of the second century of our era and was contemporary with Galen. Unlike the Empirics, Methodists, and most other Pneumatists, he paid great attention to anatomy, and his knowledge in this department was far superior to that of his predecessors; thus he thought the lung was insensitive, made of some substance like wool, provided with a very small number of nerves, and entirely devoid of muscles. On the other hand, the pleura was endowed with a high degree of sensibility and was the seat of the pain in inflammation of the chest, when the patient experiences keen suffering. It was, he said, in consequence of the insensibility of the lung that phthisical patients retained so much hopefulness as they approached the end of their existence. He credited the heart with far greater pathological significance than any other author, and syncope, of which he gives an excellent description, he considered to be a cardiac affection.

Aretaeus in his dignity, integrity, and love of his art, was a true disciple of Hippocrates. He differed from Hippocrates in thinking that the physician should attend even cases of incurable disease, though he might be able to do nothing but express sympathy. Next to Hippocrates he was the best observer in antiquity, and seems himself to have seen nearly all the diseases of which he gives so clear and graphic a description. Like Hippocrates, too, he laid stress on individual differences of constitution and of climate and on the changes of the seasons. Like the rest of the Pneumatist school he often derived diseases and their symptoms from the temperature of the elements; among others, he found in cold and dryness the causes of old age and of death—indeed he made various chronic affections issue from the cold and damp. The liver he thought to be the organ assigned by Nature for the preparation of the blood, and, like the rest of the ancients, he made this viscus the seat of desire.

We have seen how the Dogmatists were influenced by Plato, the Empirical school by the Sceptics, the Methodists by the Epicureans, and now, finally, it was the most fashionable philosophy of the Roman world—namely, Stoicism—which exercised most influence over the school of the Pneumatists. The whole idea of the *Pneuma*, at least the elaboration of it, was, of course, Stoic in origin. No doubt the Hippocratic idea of innate heat was something of the same nature, and the same idea in later times may be found in the *Archæus* of Van Helmont, though that was perhaps a more mystical conception, and even indeed in the *élan vital* of Bergson. But the Stoics, like the Epicureans, were not primarily interested in physics or in theories about the *Cosmos*, nor did they have any high opinion of medicine, for their essential aim was to find some philosophic basis for the guidance of everyday life—how, in fact, life was to be lived rationally and nobly in the world; unlike the monastic ideal of the Middle Ages, which was rather how life was to be lived out of the world. Zeno, the founder of the Stoic school of philosophy, some three hundred years before the epoch we are now considering had endeavoured to discover for men a way of escape from fear and desire by adjusting their wills to everything which might befall them. "I am happy," he said, "when I do not want things to be any other than they are."

According to Zeno the world was governed by the same divine reason which dwells in the breast of each individual, and the universe, animated by this reason, was striving to realize values which the human reason would appreciate as good if it could but know the whole. Human reason coincided with the universal reason which governs nature, and this indeed, according to Zeno, was the source of the moral law. To establish a physical basis for his ethics Zeno went back to Heraclitus and believed that all individual things in the world are only oppositions of one and the same thing, and that there is but one law which governs the course of nature and ought to govern the actions of man. The ultimately real was regarded by the Stoics as corporeal, and spoken of as warm vapour or fire, for it is warmth which begets, enlivens, and moves all things.

The essential aim of the Stoic physics was to show that the power operating in the universe was rational; Zeno believed in a rational process controlling the world. When Zeno said, "God is body," he showed his repugnance to any teaching which would dissolve God into an abstract idea; it was the crude expression of an intense conviction that God was real, was indeed concrete. For the Stoics the universe was a living being, and we should therefore regard their doctrine as pantheistic rather than materialistic. Chrysippus, a successor of Zeno, was of opinion that without the study of physics it was not possible to distinguish between good and evil, yet, as a matter of fact, the Stoics did not really go very deeply into the question of physics and investigation of nature.

As we have seen in the case of the Epicureans, so too with the Stoics the free and purely scientific contemplation of the world which characterized the old Ionian philosophers had disappeared coincidentally with the loss of political freedom due to the rise of the Macedonian hegemony, and the chief value of philosophy was sought more and more in the refuge with which it provided men against the miseries of life. The concentration, then, of Stoicism upon conduct and the moral life is perhaps its chief title to fame. It cannot therefore be said that the Pneumatist school of medicine received any great stimulus to the investigation of nature from the Stoic philosophers, but what it did receive was a belief in a rational principle pervading nature—that, indeed, nature is governed by rational laws, to which it is the business of man to accommodate himself. Such a belief was undoubtedly a source of stability to the intellectual life of those physicians among the Pneumatists who unconsciously followed the Stoic teaching and raised them to a loftier mental standpoint than that occupied by the Empirics and Methodists.

In the long run the belief in reason can hardly fail to have a favourable influence on the progress of medicine, and therefore the Stoic philosophy offered this indirect help to medicine. But Stoicism, in ordinary parlance, calls up the vision of rather hard, unamiable people, indifferent to all outward things, careless alike of the major and minor aesthetics of life, and clad in an impenetrable carapace of spiritual pride. This picture of the Stoics has been drawn by all the world's satirists from Horace onwards. Yet it is not a true picture till we come to the later phases of Stoicism, when that philosophy was passing into the unpleasing eccentricities of the monastic ascetic. The earlier Stoics, with whom we are more concerned, busied themselves but little with physics and the structure of the external world, but they were not averse from a life of action, they maintained an ideal of civic virtue, and had not learnt to be indifferent to the welfare of the State, even though a somewhat abstract cosmopolitanism was teaching them to transcend the limits of nationality. The medical school of Pneumatists seems to me to have been exceptionally free from the taint of charlatanism and to have maintained an ethical standard distinctly above the average of the profession in their day. Is it unduly fanciful to imagine that the noble moral grandeur which characterized the great Stoics, such as Seneca, Marcus Aurelius, and Epictetus, may have instilled itself into the physicians of the Pneumatic school?

A CONGRESS of French-speaking neurologists and alienists will be held at Besançon in August under the presidency of Dr. Henri Colin. The subjects to be discussed will include psycho-analysis, crimes resulting from narcomania, and nervous trouble resulting from supernumerary ribs.

A SOCIETY has been organized at Copenhagen to endow Pasteur scholarships for Danish medical men who desire to take courses of study at the Paris Pasteur Institute or at similar institutions in other countries; Dr. S. P. L. Sorensen was elected president of the society.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## ACUTE OEDEMA OF THE CERVIX.

THE following case may be of interest in connexion with the report of the Edinburgh Obstetrical Society (BRITISH MEDICAL JOURNAL, January 6th, p. 18).

On December 4th, 1922, I was called to a young married woman aged 28 (her first child); she had been in labour for six hours. Examination showed a single pregnancy at full time in the left occipito-anterior position. On vaginal examination the os was dilated to the size of a five-shilling piece, and the membranes were bulging; the anterior lip of the cervix was swollen but was not lower than the posterior lip. One and a half hours afterwards the head was on the perineum, and the child (weighing 6½ lb.) was born without any difficulty twenty minutes later. As haemorrhage was profuse and continuous I endeavoured to express the placenta, when the large oedematous anterior lip of the cervix protruded. It was the size of a large orange, and instead of the placenta a large clot, as big as a foetal head, was expressed. As the haemorrhage still continued I removed the placenta manually without difficulty, when the haemorrhage ceased and the uterus contracted down. From the size of the anterior lip of the cervix I was surprised that there had been no arrest of the head.

The puerperium was slightly protracted but was uneventful; two weeks afterwards the anterior lip was still to be seen within the vulva, but four weeks from the date of birth it had receded, was patulous, and was about half an inch lower than the posterior lip. I notice that the reported cases are all multiparæ. This patient aborted two years previously at the tenth week; she was then in a weak and anaemic condition, but responded well to treatment. I had never previously seen the condition, and although recognizing it to be rare I was unaware that it was so rare as stated.

J. A. MCKINNON.

Ipswich.

## ERYSIPELAS OF THE MOUTH.

THE case of erysipelas of the fauces published in the JOURNAL of January 20th (p. 105) reminds me of a case I saw some years ago. The interesting point in it, apart from the comparative rarity of the condition, was the spread of the infection to the face by way of the Eustachian tubes.

The patient, Mrs. H., seven months pregnant, when seen was complaining of sore throat and swelling of the neck. On examining her throat I thought she was suffering from diphtheria; I also noticed that the fauces were more of a dusky red colour than usual. The report on the swab was, however, negative. In about three days' time both ears became affected with erysipelas, the infection evidently having spread from the throat by way of the Eustachian tubes. From the ears the infection gradually spread over the whole face, and was of so severe a nature that for eight days she was quite unable to open her eyes.

The patient made a good recovery and had a perfectly normal confinement at full term.

Kempston, Bedford.

GEORGE BUTTERS, M.B.

## FRACTURE OF THE NECK OF THE RADIUS.

FRACTURE of the neck of the radius is sufficiently uncommon to warrant the following record of a case.
